## THE CROONIAN LECTURES

FOR 1839.

BY JOHN CLENDINNING, A.M. & M.D.

Of Oxford, &c.

*As delivered at the Royal College of Physicians,  
May 15, 17, 22.*

*Connection of the Croonian Lectures of 1838  
and 1839—Diagnosis of diseases of the heart  
—Preliminary remarks—Principal forms of  
cardiac disease—Passive aneurism of the  
ventricles—Volume of the heart in disease—  
Mechanical diagnosis—Percussion.*

IN the Croonian Lectures for 1838, I had the honour to lay before the College a series of facts that had fallen under my observation during the two or three previous years, and which appeared to me to possess a sufficient degree of interest and importance in their relations to the pathology of the heart, to warrant my publishing them in those lectures to the profession. The facts I refer to, it will perhaps be in the recollection of some, if not all now present, consisted chiefly of measurements, by weight and bulk, of the heart, encephalon, and other fleshy or solid viscera; and of the lungs and stomach amongst the more porous or hollow organs. The facts in question were classified according to age and sex in all cases, and, to some extent, according to disease; and were presented in tabular forms, and for the most part in figures denoting the average ages and weights of the several classes of subjects. I may here mention, that since March or April last, at which time I was obliged to close my numerical analysis of observations *post mortem*, in getting ready my tables for the inspection of my colleagues in this theatre, I have, as opportunity offered, continued

the same method of research by weight and measure; and though more interrupted than in former years, owing to official misunderstandings and circumstances thence arising, I have, notwithstanding, in that period, obtained probably some 200 observations, leading, so far as examined, to results precisely similar to those to which I was led by the 500 and odd observations already referred to.

*Main objects had in view in the lectures for 1838.*—In presenting the facts last year to the notice of the College, I took occasion to remark, that they were sought for, collected, and analysed, without any preconceived views, and were then brought forward, not to substantiate any foregone conclusions of my own as to the diseases of the heart or of any other viscera, but to shew, by what to me appeared a scientifically unexceptionable method—

First,—that certain opinions extensively prevalent with regard to the causes, signs, and pathological relations of morbus cordis, were more or less erroneous, and that the morbid influence of the diseased heart was probably very much more important, and the frequency of morbid alteration of the heart very much more frequent, than distinguished pathologists seemed to me to be aware of; the former (cardiac morbid influence) extending, in well developed morbus cordis, to all or most of the other viscera, and producing in them habitual congestions, and ultimately hypertrophies and enlargements, and other morbid condition; and the latter (organic cardiac disease) becoming, from rare in early life, more and more frequent after maturity, and at length towards and during the decline of life taking the lead both for frequency and importance, of probably all other organic diseases. The facts stated went to shew further, that the principal anatomical element in cardiac diseases is hypertrophy,

or increase of muscular substance; and that morbus cordis with muscular atrophy is so rare, as to be, if not absolutely, at least comparatively and practically, a nullity nearly; and that the importance of cardiac valvular disease has been much over rated, principally owing to neglect of accurate instrumental means of measuring the heart's development in pathological examinations, and partly, possibly, also to that facility with which even the most wary and sceptical minds are not unfrequently induced to accept of the suggestions of educational systems and theoretical prepossessions as genuine inferences from observation.

Secondly, and a second and subordinate but yet important object in detailing those facts, was to show, that, in addition to the means generally employed in the anatomical investigation of organic diseases more especially, it was desirable that other and more accurate means, hitherto rarely resorted to, should be employed; and that for the examination, in particular, of that most common form of grave organic mischief, namely, visceral hypertrophy, the aid of instruments calculated to detect deviations as to weight and volume, was necessary to correct the capriciousness, and prevent the errors incidental to all estimates founded on simple inspection and manipulation of the viscera. The details of the facts on that occasion, adduced for the double purpose just stated, have been for some time in print, in the pages of the *MEDICAL GAZETTE* (vol. ii. 1838) and *British Medical Almanack* (1839), and require at present no further notice, probably, than the summary sketch of their character and scope above taken.

*General visceral hypertrophy and cardiac asthenia in morbus cordis, also insisted on in 1838.*—After stating those facts, therefore, I concluded my lectures with an attempt to account for the visceral irregularities shewn by my observations, and confirmed by those of various distinguished authors, which were quoted for the purpose, to accompany ordinarily the chronic diseases of the heart; and amongst the causes experimentally or conjecturally assigned, I insisted especially on an adynamic condition supervening on the hypertrophous heart, at a frequently early stage—if not present from the commencement—an asthenic or adynamic condition, which I argued must operate disadvantageously, by favouring visceral congestion, habituating the organs to a plethoric condition, and exciting in them abnormal nutritive action, leading, when once established, to hypertrophy with enlargement, or else to the still worse mischief of increase of density and induration.

Beyond the subject just named, viz. cardiac debility or inertia, and its consequences to other organs in morbus cordis, I was unable to proceed, within the limits of one Croonian series, and was obliged to close without noticing any of several other topics of importance suggested by my observations, and having reference principally to diagnosis and treatment. Some of the subjects, on that occasion of necessity passed over, I mean on this to treat of at such length as my time will permit, wishing it always to be borne in mind, that it is not respecting the diagnosis in general, or treatment generally, that I mean to speak, but of cardiac semeiology and treatment so far as those appear to receive illustration from my own observations and experiments.

*Explanation with reference to valvular disease as a cause of morbus cordis.*—But before entering on the subject of diagnosis, I beg leave to make a few observations on the subject of valvular disease as a cause of morbus cordis. This subject was treated of in my second lecture of last year, but so briefly and hurriedly, owing to press of matter, that the meaning of the lecturer was but very equivocally conveyed in more than one point; and I think it desirable to avail myself of this opportunity of explaining more clearly the inferences on that head, that appear to me legitimately deducible from my experiments and observations. In my first lecture, I stated I had not found valvular disease in more than about one-sixth of the cases of morbus cordis, in a total of between 170 and 180 cases, examined without selection post-mortem; and assuming—1. that equivalent contrary observations could not exist, owing to the general neglect of the balance in pathological researches; and 2. that hypertrophy of the heart is common without valvular disease, and valvular disease almost unknown without hypertrophy, &c. &c. I felt myself warranted in assigning to valvular disease a very small share of influence in the production of the structural lesions that constitute morbus cordis. But in replying to the question, how is valvular disease related to morbus cordis, or muscular hypertrophy, if not as a cause? I expressed myself with so much brevity as to obscure my own meaning,—whence the necessity of the present explanation. The passage, as delivered and printed, ran nearly thus:—“Hypertrophy results from vital causes exclusively, and not from mechanical ones; and the more usual result of the action of those causes, where sudden and intense, is inflammation; but when moderate and gradual, they rather produce hypertrophy—a condition akin to inflammation, and one that augments enormously the susceptibility of

the inflammatory process with which every part is normally endowed. Now to such supposed hypertrophy as the limit beyond which the operation of the vital causes referred to does not ordinarily pass, and to the morbid susceptibility of inflammation in every part too plentifully supplied with nutrient fluids, which such hypertrophy implies, I would refer almost all valvular disease occurring in mature years, especially in males, and such as could not be attributed to obvious causes, as falls, blows, or well-marked cardiac rheumatism, &c. I would thus in great part reverse the order of causation usually received, and attribute much of the valvular disease to inflammation, mainly induced, if rheumatism be excluded, by previous hypertrophy, as a most potent predisposing cause."

*Intended meaning of the passage.*—In the passage just cited, my meaning was, that muscular hypertrophy was related to valvular degeneration rather as a cause, however indirect, than as an effect. I conceived that what I might venture to call the sub-inflammatory process of over-nutrition, or hypertrophy with thickening, &c. was greatly more frequent in the parietes of the heart than in the valves; and that the latter, more rarely primarily affected, were most frequently altered by a sub-inflammatory action extending from the previously hypertrophous muscular substance to the ligamentous tissue of the valves;—and such continue to be my opinions. But in stating them on that occasion, I seem, judging by my printed lectures, to vacillate between something like the doctrine apparently held by several pathologists, viz. that endo-carditic inflammation arising from rheumatism, and producing disease of the valves, is the starting point in most cases of chronic morbus cordis,—and my own view, which places valvular disease in a very subordinate position; and the ambiguity of the passage was increased by repeated reference to rheumatism as a cause of morbus cordis.

*Precise views of the author.*—Now with respect to the mutual ætiological relations of valvular disease and muscular hypertrophy, the probable truth, so far as I have been able to decipher it, is shortly this. The muscular substance is the favourite seat of morbus cordis, and there it usually begins in the form of simple hypertrophy. From the parietes of the heart the abnormal nutritive action extends to the valves and interior lining membrane, and to the muscular tunic and exterior pericardium. The evidence of such compensating extension is this:—In

the enlarged heart the valves are deeper and wider (and often very much ampler in both directions), as well as thicker often, and less transparent, though still abundantly flexible, than in the normal heart. From their sufficient amplitude of depth and width, notwithstanding the expansion of the cavities and passages, and from the absence, in most cases, of evidence during life of valvular defect, the conclusion seems inevitable that the valves must grow in depth and width as the muscular fibres increase in length and thickness. This conclusion is strengthened by the frequent manifest increase of opacity and thickness of the valvular laminae; also by the greater frequency and extent of those opaque spots, and often by general increased opacity of the investing and exterior layers of the pericardium. In a heart which is the seat of the over-nutrition in every tissue which I have just described, the occurrence of alterations producing well-marked functional incapacity, is easily understood. The muscular tissue, it is well known, is little liable to any other morbid change in structure than increase of volume or hypertrophy. But not so the membranous structures of the valves, and interior and exterior tunics of the heart. In those, an excessive nutrition is capable of producing other very important changes, even without amounting to inflammation. But it is in the laminae of the valves that the physiological importance of those changes is specially important. In the valves, a very moderate increase of density is capable of compromising seriously their functional capacity. Induration seems usually to include diminution of flexibility, and not unfrequently shrinking or contraction also; and a valve having even a single lamina too short, or too shallow, or too rigid, is no longer equal to what, in the language of engineering, may be called its "duty."

In addition to the mischiefs just pointed out, as likely to arise from the existence of simple excess of nutritive action in the valves, it is not to be forgotten that a peculiar liability to inflammation attends the hypertrophous state. Hence, while the parietes are found simply hypertrophous, we, in a considerable number of cases, find the valvular tissue extensively vitiated—viz. indurated, contracted, osseous, puckered, nodulated at the edges, or otherwise incapacitated; and at the same time, in a smaller but yet considerable proportion of cases, we find the pericardium either disfigured by organized exudations of lymph, which give rise to adhesions, or else projecting from its surface, deprive it of its usual polished smoothness; or by

depositions in or under the muscular tunie, or in the substance of the exterior loose layer, of the sac.

*Additional considerations.*—Such are the inferences at which I have arrived as to the more usual relation between muscular and valvular hypertrophy in morbus cordis, and such are the experimental facts from which those inferences are directly deduced. But those are not the only grounds of the conclusions stated.

1. To those might be added the opposite laws that seem to govern the distribution of acute rheumatism and morbus cordis, in their relations to age. Acute rheumatism is, I think, generally held to be a disease of youth and manhood, rather than of declining years; while I have, I conceive, rendered it probable that morbus cordis becomes more frequent precisely as life wanes; being more rare in manhood than in age, and in boyhood more rare than in vigorous manhood. If this contrast be well founded, it seems clear that the impression that rheumatic inflammation is a principal remote cause of morbus cordis, in the large sense of the word as used in these lectures, is but indifferently well founded.

2. We might also add to the preceding reasons, the comparative rarity of pericarditic appearances in the chests of subjects of morbus cordis. According to my observations, we have, for one case of morbus cordis involving pericarditic adhesions or depositions, at least eight or ten cases of cardiac chronic disease, presenting no traces whatsoever of pericardial inflammation. In this, also, my views differ widely from those of Professor Bouillaud and others; and with respect to endo-carditis, I have come to a like opposite conclusion.

3. To the above-stated considerations, opposed to the valvular origin of morbus cordis, might be added the excessive frequency of disease of the right ventricle, when compared with disease of its valves. But having sufficiently explained what I said so obscurely, because, with so much compression and brevity, last year, it is unnecessary to dwell longer on this subject on the present occasion. Suffice it to say, in conclusion, that while, with a full conviction from my own observation of its truth, I subscribe to the opinion that valvular disease arising in an otherwise normal heart would almost of necessity be followed by muscular hypertrophy, and that adhesion of the pericardium, or other pericardial disease capable of embarrassing the cardiac action, would prove equally effective in producing disease of the parietes and cavities, I still see no reason for believing that valvular defect or pericardial adhe-

sions can be considered as the principal, much less the only remote causes of cardiac hypertrophy, or for doubting that the great exciting cause or causes of the excessive muscular development in morbus cordis remains still to be discovered.

*Conjecture of the lecturer.*—And on this subject, if I were to hazard a conjectural anticipation of the results of future demonstrations, I should say this:—All men are naturally susceptible of cardiac muscular hypertrophy, as of every other disease, when exposed to exciting causes of sufficient energy. But of any number of persons, however favourably circumstanced for the production of the disease, but a fractional part has ever been known to suffer from it. To account for such a difference of results, different degrees of susceptibility are easily admitted, and, upon persevering analysis, the final result is, that men differ in original conformation and capacities; so that one man, temperate and prudent in all things, shall, without obvious cause, become a subject of morbus cordis,—and another, cautious and moderate in nothing, and perhaps, further, much exposed to unavoidable unfavourable influences, shall reach an advanced age with the heart in a condition perfectly normal. Now the great source of that light hitherto withheld from the great and paramount department of pathology which embraces the causes of disease, must, I conceive, be the law that governs those differences of original conformation and vital power just alluded to; and so long as the varying amounts and relations of primary influences so uncertain as those differences shall continue, as at present, wholly conjectural, and without tests to identify or constants to measure them, there seems not much reason to regard much (and probably the greater part) of our aetiological illustrations of disease as any thing better than, in some cases, ingenious speculations and surmises, and in a majority of instances, hypothetical rubbish.

I now enter on the chief business of these lectures—viz. the diagnosis of cardiac disease.

*Diagnosis of morbus cordis.*—The semeiology seems the only part of the scientific history of disease of the heart in which, as yet, any considerable progress has been made. Centuries before the cardiac pathology was at all appreciated, considerable progress had been made in the anatomical and physiological history of pulmonary disease. The general uses and high importance of the lungs, must, from the nature of things, have been obvious to the earliest and rudest physiological observers;

so that the attention of pathological inquirers must have been directed to the respiratory organs from the earliest times. With respect to the heart, however, it is well known that a correct appreciation of the importance of that organ could not well be looked for prior to the discoveries of Harvey. Up to his time, it was not so well understood as it has now become, that amongst the most urgent wants of organic life, was to be reckoned an unceasing interchange of blood between the lungs and the rest of the animal frame, and in all parts a constant progressive motion from artery to vein, and from vein to artery, around the vascular circle; and equally little was the great truth known, that of all this unintermitting locomotion, and of these alternating conditions of the fluids, as well as of their general circular movement, the heart was the central agent and certain mainspring.

To such ignorance of the functions of that great instrument of animal life, the heart, we must, I presume, refer the inattention to its pathology of the earlier observers. And on referring to the collections even of those that have written since the middle of the seventeenth century, we find little or no notice of other forms of disease of the heart, almost, than excessive hydro-pericardium, suppuration of the pericardial sac, adhesions of the pericardium to the heart, ossification of the valves, and sometimes of other parts, and not unfrequently the *cor bovinum*, or enormous hypertrophy of the heart, occasionally and but rarely met with. Of the comparatively moderate hypertrophy, which seems to me so common as to exceed in frequency, many times over, all other forms of cardiac disease, and which, though not so hopeless as many other forms of morbus cordis, is, it must be admitted, a very grave and formidable structural lesion, we find in those writers almost no trace. Even in more recent writers and authors of the last fifty or sixty years, there is great want of precise information as to the distinctive characters, whether anatomical or semiological, of cardiac disease; nor do I think that before Laennec's discoveries it was possible, with certainty, to diagnose morbus cordis in the greater number of cases, that is to say, when the hypertrophy was not great, nor the heart's action vigorous. The addition, however, now some twenty years since, of Laennec's method of investigation to that of Avenbrugger, has enormously increased our means and facilities for the detection of morbus cordis, which is now amongst the most easily and certainly detected of organic diseases. Now the points of view in which

the results of my researches (assuming at present their correctness as close approximations) have important bearings on cardiac diagnosis, are numerous, and some of them in strict accordance with prevalent opinions, but to others, unfortunately opposed more or less to them. To the consideration *seriatim* of those topics, it becomes now my duty to advert.

*Preliminary remarks respecting passive aneurism and diseases of the auricles.*—Before entering, however, on the particulars of any of those topics relating to cardiac diagnosis, it is necessary, or at least convenient, that I should offer some preliminary observations, in order to explain why, in my enumeration of the species of heart disease that require each for itself a distinct account of its diagnostic symptoms, I pass over some topics much enlarged upon by preceding writers, and considered apparently of great importance. The topics I refer to are the varieties observed in morbus cordis, arising out of differences in different instances, in the distribution of the hypertrophy and enlargement; that condition being sometimes, it has been held, altogether wanting, but in most cases present, though not always equally divided between the sides and cavities. And in the first place, let me guard myself against the suspicion of an unworthy desire to depreciate the meritorious and most useful labours of descriptive pathologists, by stating that I fully admit the existence, abstractedly considered, of almost every variety of heart disease pointed out by those who have studied the heart most exclusively after the Natural-History method; and in the second place, that I acknowledge that most of the varieties described are of great importance, and such as to warrant fully the most elaborate descriptive histories that have been given of them.

*Principal forms of morbus cordis.*—With respect now to those various forms of disease themselves, I should say that the first, in frequency and importance, is the hypertrophy, with enlargement of the left ventricle—a morbid condition of vast interest, and upon which, in its sthenic stage, several recent cardiologists, and amongst others Dr. Hope and Dr. Copland, have dilated very instructively. Next comes the like condition of the right ventricle. This is of much inferior importance to the former; for though apparent enlargement is common enough, enlargement with well-marked hypertrophy is, I think, comparatively unfrequent. After these, follow in frequency and importance the valvular class of cases, a class nearly always involving hypertrophy and enlargement of the left ventricle at least,

and, indeed, in most cases of both ventricles. After these should follow the diseases of the auricles, and then dilatations of cavities, not including augmented nutrition and parietal thickening.

*Passive aneurism of the ventricles and disease of the auricles unimportant.*—But with respect to those two latter classes I must say, that I doubt, if I do not deny, the existence of the last class, and the importance of either class. Enlargement, with thinning of the walls, has been supposed to occur in all the cavities, though most frequently in those of the right side. To such enlargement, with thinning in the ventricles, has been ascribed the feebleness of the heart's thro, and of the arterial pulse, so often met with in cases of great enlargement. To the same cause have been attributed certain abnormal peculiarities in the character and audible extent of the cardiac sounds, viz. that the sounds of systole and diastole, but especially of the former, have been found shorter in time and shriller in tone than normal; and that the whole cardiac effort has been completed more rapidly and closed more abruptly, so that the enlarged but attenuated adult heart has rendered sounds, short, clear, and sharply defined, almost as those of the heart of a child. To this enlarged and attenuated condition have further been ascribed very important pathological consequences, presumed *mediate* results of debility in the central organ, and *immediate* effects of embarrassment and irregularity in the remoter and minuter channels, but especially in the venous circulation.

To the dilatation, with or without thickening of the auricles likewise, important consequences have been attributed; and supposing the auricles, or either of them, to propel blood too plentifully or forcibly, the corresponding ventricle, it is easily understood, would quickly feel and react on the increased stimulation, and ventricular hypertrophy and enlargement would probably result. On the same grounds it might also be apprehended that abnormal expulsive efforts in the auricles might greatly embarrass, as the case might be, either the greater or lesser circulations, or both together, by causing regurgitation into the valveless cava, or equally patenscent veins of the lungs, or into both sets of veins at the same time. From a condition of the auricles opposite to vigorous action, viz. inertia or debility, also, important inconveniences might be conceived to arise both to the ventricular functions and venous circulation.

With regard to the latter, or disease of the auricles, however, it is first to be noted that there are no pathological observations, so far as I know, that

substantiate the claims that have been advanced on their part, as important or morbid conditions. Those claims, speaking of them generally, have been apparently deduced rather from theory than experience. In a considerable proportion certainly, and I suspect in the great majority of supposed dilatations with attenuation, or at least without observed hypertrophy, the loss of muscular substance has been apparent only, and not real. This condition occurs usually on the right side, and is the result of a slow death, partly owing to the superior tenacity of life of the right auricle and of the right cavities, probably in common, and to the consequently more tardy arrival in those cavities of inertia and cadaveric rigidity; and owing partly also to previous congestion, and at length complete stagnation, in the vessels of the lungs, in consequence of the complete cessation of the normal efforts of the respiratory muscles, while the veins still continued to pour into the auricle their distending humors.

*Physiological arguments continued.*—To the absence of unequivocal pathological evidence may be added the want of physiological facts to shew that the auricle contributes in any such manner as pathologists have supposed, towards either section of the general circulation. The auricles, it may be urged, are muscular and contractile; and further, that in experiments on living hearts *in situ*, and *out of the body*, they have occasionally, by myself and others, been seen to contract and expand alternately, being, when examined in action *in situ*, found to fill with blood in their diastole, and become hard and small in systole, in like manner with the ventricles. It is, however, notwithstanding such facts, very unlikely that the auricles contribute in any very important degree as contractile organs to the cardiac circulation, or that they are any thing other, practically, than extensions of the veins respectively, and *diverticula* or contrivances to provide against contingent irregularities in the ventricular action or venous currents. That they are no more than just stated seems sufficiently probable, from this circumstance alone, that they are unprovided with any valvular structures sufficient to prevent reflux into the veins; and with respect to the latter canals are, in fact, in a constantly patenscent state, admitting, apparently, so far as their exterior orifices are concerned, with equal facility, influx from without and efflux from within their cavities. Now such a state in an organ acting like a ventricle would seem adapted for no end so completely as that of embarrassing the *vena cava*, and consequently retarding and

deranging the main current in the first instance, and afterwards the smaller affluents of the venous circulation. Add to this the fact, that in the great majority of observations on the living heart, whether *in situ* or out of the body, no action resembling either systole or diastole has been perceptible in the auricles, even during the uninterrupted continuance of the normal alternations of action in the ventricles. On the whole, then, there seems to be neither in pathology nor physiology any sufficient reason for attaching much comparative importance to the auricles.

With respect to dilatation with attenuation of the heart's cavities, it is in any event, as it regards the ventricles, if not apparent only, at least too rare to possess any great interest, or require much notice in a large view and general account, such as this of cardiac morbid development. Genuine organic disease, then, of the auricles, and passive cardiac aneurism or dilatation with attenuation of the ventricles, if I rightly interpret, the facts that I find recorded, or have myself observed, are so unfrequent as to be, for all practical purposes, when compared with other forms of cardiac disease, unimportant. I conceive, therefore, that I have had sufficient warrant for so slightly noticing them, and might, perhaps, without great impropriety, have wholly omitted the consideration of them.

*Additional reasons.*—Two additional reasons might be added, if more were needed. One is this: the diseases of the auricles and the passive aneurism of the ventricles, are not distinguishable by any means that I know of, from other more important diseases of the heart. Those of the auricles, I believe, have never been supposed to possess diagnostic signs, at least since the negative character of their functions has been generally recognized. But not so the attenuated enlargement of the ventricles; for with regard to that form of *morbus cordis*, the opinions of Corvisart and Laennec are still prevalent traditions in the profession. Indeed, since the discovery of the true causes of the heart's sounds through the researches of Drs. Carswell, Rouanet, Billing, Hope, Williams, and other distinguished experimentalists and observers, foreign and domestic, the doctrine of passive cardiac aneurism (or enlargement with attenuation) has become even more completely incorporated with our nosological systems and elementary medical literature than before; being now provided with a proper etiology and semeiology, accommodated to the most recent and improved physiological researches. On this account, notwithstanding the manifest inconveniences of repetition, I could not avoid here making a few short remarks

before passing on to the next topic, were it not that another opportunity will present itself under the head of the sounds of the systole and diastole, and the diffusion of those sounds over the parietes of the chest.

*Mechanical diagnosis of morbus cordis.*—There is a general impression, I think, among pathologists, that, in the majority of cases of chronic disease of the heart, there is increase of volume in that organ. This remark applies equally to those cases in which the heart is supposed to be increased in volume or size only, without any increase in substance or weight. Now this prevalent opinion corresponds entirely, so far as it goes, with the results of my own experiments and observations. By very numerous trials, by weight and measure, in air and water, I found experimentally that the diseased heart nearly always exceeds in linear dimensions the normal standard; the exceptions being rare, and consisting almost exclusively of cases of concentric hypertrophy, or spastic contraction of the left ventricle, especially occurring during the agony apparently, and rendered permanent by speedily supervening cadaveric rigidity.

The first and most obvious and direct method of ascertaining the development of the heart is, therefore, the measuring of the extent of the dulness of the præcordial resonance by percussion, and observing the area over which the cardiac impulse is perceptible to the hand. Also, by inquiring whether the systolic and diastolic sounds can be heard in distant parts; as behind over the middle or lower lobes, or on the right side of the sternum. When the heart contracts with energy, there is further to be noted the momentum of its impulse, which, in sthenic hypertrophies, is often the most satisfactory of all the signs.

*Percussion.*—Now with respect to the first, or the direct linear measurement, if I may so call it, by percussion, the ease and certainty of this method is, in favourably circumstanced cases, quite admirable. By laying the hand across the præcordia, with the fingers spread out in a radiated manner, and striking on each of them in turn, as on a pleximeter, it is possible, in many cases, to measure with surprising accuracy the dimensions of the heart in the transverse direction; but it is necessary that the lungs be sufficiently porous, that is, free from phthisical or pneumonic indurations in the parts immediately beyond the heart's outline, in order that the difference of resonance be satisfactory. By striking on the outspread fingers, as above described, I have in numerous instances been able to satisfy myself in a few moments of the

heart's excess of volume, the dulness being very often perceptible from the edge of the sternum to the nipple and beyond. But in examining by percussion, in the vertical direction, the difficulty is greater to fix on the limit sought for. In the upper limit of the cardiac region, doubtless a difference of resonance is usually easily obtained that points out at once the extent to which the heart is developed in that direction. But the difficulty respects the determination of the inferior boundary of the cardiac dulness, from detecting which we are prevented in different instances by the stomach or the liver, the former, or stomach, embarrassing us with a resonance often equalling or rather exceeding that of the central parts of the lungs, at a point where little or no pulmonary substance exists; the latter, or liver, rising in a different and posterior plane, but to as high a level as the lower part of the heart, so that no sensible interval of pulmonary resonance divides the cardiac from the hepatic regions. To supply the want of such a space of pulmonary resonance, it has been proposed to assume that on the left side the height of the diaphragm corresponds in all cases nearly with that on the right side, where what, in a communication to the *MED. GAZ.* for Jan. 7, 1837, I have ventured to call the *summit level* of the diaphragm, is easily determined, and may indeed, as Dr. Edwin Harrison has pointed out, be known by simple inspection or application of the hand; and with this assistance it may be possible to measure the living heart in the vertical direction as accurately as in the transverse. But though a collaborateur of Dr. Harrison's in certain decisive experiments, of which, as above stated, I communicated the particulars to the *MEDICAL GAZETTE*, and which were made *in mortuo*, with a view to ascertain the practicability of determining *in vivo*, by simple means, the height to which the liver rises under and behind the ribs, I have not made much use of the results of those experiments, or at any rate have not been careful to record a sufficiency of facts relating to the point, to entitle me now to give a decided opinion.

With respect to the upper boundary of the heart's position, there is occasionally a source of difficulty in consolidation of superior parts of the lung, which makes the contrast in resonance that we seek too narrow to be perceived; or in an emphysematous condition, by the excessive resonance of which the dulness of the cardiac sound is more or less compensated for, and consequently masked; and this latter source of error not rarely extends through the whole cardiac region.

Owing to one or more of these sources

of fallacy, it is very frequently not practicable to diagnosticate with certainty, in cases of enlargement, by unaided percussion of the præcordia. Of this, Corvisart, Piorry, and Bonilland, who have paid most attention to this point of cardiac semeiology, seemed to have been fully aware, to judge by the care with which they enumerate and describe such other conditions as appeared to them of any value as signs of disease of the heart.

## CLINICAL REPORTS

OF

## DIFFICULT CASES IN MIDWIFERY.

By ROBERT LEE, M.D., F.R.S.

Physician to the British Lying-in Hospital, and  
Lecturer on Midwifery at St. George's  
Hospital.

### FIFTH REPORT\*.

#### *Cases of Distortion of the Pelvis in which Premature Labour was induced.*

CASE CXI.—At 8 P.M., 16th April, 1831, I was called to a patient residing at 4, Brewer Street, who had been in labour with her fourth child the greater part of the day. I found the orifice widely dilated, but the membranes were unruptured, and the presenting part was beyond the reach of the finger. At 10 P.M. I ruptured the membranes, and ascertained that the presentation was natural. The pains were strong and regular, and continued to return at short intervals till 3 o'clock on the following morning, when they began gradually to diminish in strength and frequency. At 6 A.M. the pains had wholly gone off, and the head was firmly impacted in the brim of the pelvis, and much swollen. The pulse was frequent and feeble, and all the usual symptoms of exhaustion were present. At 7 A.M. Dr. H. Davies saw the patient, and agreed with us in thinking that immediate delivery by craniotomy was necessary. After opening the head I found little difficulty in extracting it with the crotchet. No bad symptom followed.

I afterwards learned that this woman had been delivered of her first child by the same means.

At the end of the seventh month of her second pregnancy labour came on

\* For the preceding Reports see the volume just concluded.

spontaneously, and the child was born alive without artificial assistance, and has been reared.

Premature labour again came on spontaneously at the commencement of the eighth month of her third pregnancy. The nates presented, and the child was also extracted alive.

Dr. H. Davies induced premature labour at the seventh-and-a-half month of her fifth pregnancy, and the child was born alive, but died soon after in convulsions.

Occurrences similar to those observed in the preceding case must have originally suggested the idea of bringing on premature labour artificially in cases of distorted pelvis, and probably led, in 1756, to that consultation of the most eminent practitioners of midwifery in London, at which the practice was approved of, and soon after successfully carried into effect by Dr. Macaulay.

**CASE CXII.**—On the 20th of May, 1828, a woman, 29 years of age, with slight distortion of the pelvis, was admitted into the British Lying-in Hospital to have premature labour induced. Dr. H. Davies detached the membranes from the lower part of the uterus without rupturing them. Labour came on eight days after, and the nates presented. I succeeded in extracting the trunk and the extremities without much difficulty, but the head could not be drawn through the brim of the pelvis without the employment of much force for a considerable period, during which time the pulsations in the cord gradually ceased, and the child was born dead.

This patient had been six times pregnant, and had gone to the full period twice, when it was necessary to open the head of the child.

Labour came on spontaneously at the seventh-and-a-half month of her third pregnancy, after an accident, and the child was born alive, and has been reared.

Dr. H. Davies has induced premature labour three times since, at the seventh-and-a-half month of pregnancy, in this patient; but although the children have all been born alive, none of them have long survived.

**CASE CXIII.**—In the autumn of 1829 I was requested to see Mrs. —, under thirty years of age, who had been forty-eight hours in labour with her first child. The orifice of the uterus was not fully

dilated, and the vagina was swollen and tender. The head of the child presented, and it was strongly compressed by the brim of the pelvis, through which the greater part of it had still to pass. The labour pains were becoming more and more feeble, and had no effect in advancing the head. The pulse was rapid, and the strength much exhausted. As the forceps could not be applied, and immediate delivery was required, I opened the head, but the bones and integuments of the skull were much lacerated before the delivery could be completed with the crotchet. No unfavourable symptom followed.

In 1831, Mrs. — being in the seventh-and-a-half month of her second pregnancy, I resolved to induce premature labour. For this purpose I detached the membranes from the cervix of the uterus with a large bougie, the os uteri being too high up to be reached with the finger, and the separation of the membranes effected by it. A week elapsed, but no labour pains came on. I employed the bougie a second time, still more freely, but no signs of labour followed.

Dr. Merriman then saw the patient, and recommended puncturing the membranes with a slender silver catheter, much bent. I placed her upon the sofa, on the left side, with the knees drawn up to the abdomen, and separated. The exact situation of the os uteri was then ascertained with the fore finger of the right hand. Along this finger, the fore and middle fingers of the left hand were then passed up to the posterior lip of the os uteri, and in the groove formed between these fingers the point of the catheter was pushed gently forward into the orifice of the uterus, and it passed upward about three inches towards the fundus uteri, before I was sensible of any resistance produced by the membranes. The liquor amnii immediately began to flow through the catheter, when the membranes were punctured, and labour pains followed in a few hours. The labour was very tedious, but the child was at last expelled alive, and is now, in 1839, a fine healthy boy.

**CASE CXIV.**—In 1835, Mrs. W. being at the end of the seventh month of her third pregnancy, another medical practitioner was consulted, who after three unsuccessful attempts succeeded

in inducing labour. The liquor amnii did not begin to escape until a week after the last effort. The presentation of the child was preternatural, and it was still born.

CASE CXV.—On the 28th Dec. 1837, Mrs. W. being near the end of the eighth month of her fourth pregnancy, I punctured the membranes without difficulty with the stiletted catheter, which I have employed for this purpose during the last three years. The os uteri was situated very high up, and it was directed backward to the sacrum. The liquor amnii began to escape immediately after the stilette had perforated the membranes, and it continued to flow slowly during the whole of the 29th. Neither on this nor on any other of the former occasions could the presentation be ascertained when the membranes were perforated. Labour pains became strong and regular on the afternoon of the 30th, and the head presented. At 10 p.m. the head was expelled, after remaining four hours strongly compressed in the brim of the pelvis. On clearing the brim it was born in a few minutes. The child could not be made to breathe for some time, but the respiration was at last fully established, and the child lived and enjoyed good health for about a month, when, after exposure to cold, it was suddenly destroyed by inflammation of the lungs. Dr. Child was present when the membranes were perforated.

This patient did not suffer from rickets in early life, and in no other part of the body is there any appearance of distortion.

These cases are sufficient to prove that the practice of inducing premature labour at the seventh-and-a-half month of pregnancy, in slight distortion of the pelvis, is attended with little danger to the mother, and that it has been the means of preserving the lives of children who must otherwise have been sacrificed. There are many similar cases recorded by other writers in this country, which show that the strong prejudice against the induction of premature labour entertained by most continental authors is not well founded, and that the unfavourable judgment pronounced upon it by the French Academy, in 1827, ought to be reversed.

In the cases which follow, the advantage of inducing premature labour was not less striking, although the degree of distortion was so great that a child even of seven months could not be born alive. The greater number of the best practical writers on midwifery in this country have considered the induction of premature labour applicable only to cases of slighter distortion, and have considered it improper in first pregnancies, and before seven complete months of utero-gestation have elapsed. Little has been said by them respecting the safety and utility of the operation in cases of great distortion, to obviate the danger to the mother of fatal contusion or laceration of the uterus and vagina, which are always to be dreaded where much force is required to extract the head of the child.

"If the pelvis be so far reduced in its dimensions," observes Dr. Denman, "as not to allow the head of a child of such a size as to give hope of its living to pass through it, the operation cannot be attended with success. It is in those cases only in which there is a reduction of the dimensions of the pelvis to a certain degree, and not beyond that degree, that this operation ought to be proposed, or can succeed\*."

As the primary object is to preserve the life of the child, Dr. Merriman thinks the operation should never be performed till seven complete months of utero-gestation have elapsed.

As early as 1769 it was proposed by Dr. Cooper to induce abortion in cases of extreme distortion of the pelvis. "Before I conclude," he remarks, in his *History of a Fatal Case of Caesarean Section*, "allow me to propose the following question, viz.—in such cases, where it is certainly known that a mature child cannot possibly be delivered in the ordinary way alive, would it not be consistent with reason and conscience, for the preservation of the mother, as soon as it conveniently can be done, by artificial means to attempt to produce an abortion†?"

CASE CXV.—On Tuesday, 9th January, 1838, Mr. Robertson, of Jernyn Street, requested me to see a patient who was in the seventh month of her

\* Denman, vol. ii. p. 217.

† Med. Obs. and Inquiries, vol. iv. p. 261.

first pregnancy, and whose pelvis and extremities were distorted by rickets in infancy. From an examination of the pelvis, we thought that the short diameter of the brim was less than three inches, and that a child, at the full period, could not pass through it without having the volume reduced by perforation. We resolved, in consequence, to induce premature labour, though it was the first pregnancy, and though a rule had been laid down that the practice should never be adopted till experience had decidedly proved that the mother was incapable of bearing a full-grown fetus alive. I had no difficulty in perforating the membranes with the stiletted silver catheter, which I had employed before in similar cases of distortion. The liquor amnii began to escape immediately after, and continued to flow for three days; and labour pains then came on. For forty-eight hours they were feeble and irregular. Mr. Robertson then found the os uteri considerably dilated, and a foot of the child protruding through it. He extracted the trunk and extremities without difficulty; but he could not succeed in drawing the head through the brim into the cavity of the pelvis. I passed the point of the perforator up to the back part of the head without difficulty, and having made a free opening through the integuments and skull, the brain began to escape. The point of the crotchet was then introduced into the opening, and fixed upon the base; and by drawing down with it, and at the same time pulling upon the body of the child, the head soon passed through the pelvis completely flattened on the sides.

She recovered without a bad symptom. This is the only case in which I have induced premature labour in the first pregnancy.

**CASE CXVI.**—On the 17th May, 1839, when the same patient had completed the seventh month of her second pregnancy, I punctured the membranes with the stiletted catheter. The liquor amnii began to escape immediately after, and continued to flow the whole of the following day; and in the evening violent labour pains came on. The nates presented, and Mr. Robertson had no difficulty in extracting the child without perforation of the head. On the

19th the usual symptoms of ruptured uterus soon appeared, and she died on the 22d. On the 24th I examined the body with Mr. Robertson, and we found a large rent in the cervix. The pelvis is now in my collection at St. George's Hospital, and the following are its dimensions:—The distance from the base of the sacrum to the symphysis pubis measures two inches and one line. The transverse diameter of the brim is five inches and three-quarters. At the outlet a line drawn between the tuberosities of the ischia measures four inches and a half, and another line from the extremity of the coccyx to the lower edge of the symphysis pubis, three inches and a half.

Had premature labour been induced at the end of the fifth month instead of the seventh, it is very probable the unfortunate termination of this case would have been prevented. The spontaneous rupture of the uterus was produced by the great projection of the base of the sacrum.

**CASE CXVII.**—On the 5th December, 1829, the late Mr. Baker, surgeon to the St. James's Parochial Infirmary, requested me to see Mrs. Ryan, æt. 21, who had been in labour thirty-six hours. It was her first child. The head presented, but no part of it had entered the brim of the pelvis. The orifice of the uterus was about half dilated, and its margin was thin and soft. We estimated the short diameter of the brim of the pelvis at less than three inches, and the distance between the tuberosities of the ischia at two and a half. Both upper and lower extremities of this patient were bent from rickets. Four hours elapsed, after the head was perforated, before we succeeded in extracting it with the crotchet, and not till the bones of the cranium were all torn to pieces. A violent attack of uterine inflammation followed, which had nearly proved fatal.

**CASE CXVIII.**—On the 30th December, 1830, when this patient was in the eighth month of her second pregnancy, I induced premature labour by puncturing the membranes. The labour was allowed to continue till it was certain the head of the child could not enter the brim of the pelvis. The head was then perforated, and easily extracted with the crotchet. The difference between

this and the former operation was very striking.

CASE CXIX.—On the 26th April, 1832, when Mrs. R. was in the seventh-and-a-half month of her third pregnancy, I induced labour. The feet of the child presented, and the delivery was accomplished without craniotomy. Child dead.

CASE CXX.—On the 12th July, 1833, I again induced labour in this patient at the end of the seventh month. The inferior extremities again presented, and the child was still-born.

CASE CXXI.—Mrs. R. again became pregnant, and I induced labour on the 13th February, 1834, exactly seven months after the last appearance of the catamenia. The presentation was natural, and the child was born alive after a tedious labour. It lived sixteen days, and then died in convulsions. The child was extremely small.

CASE CXXII.—Mrs. R. became pregnant a sixth time, and went into the British Lying-in Hospital at the seventh-and-a-half month, where I induced premature labour by puncturing the membranes, on the 27th December, 1834. The feet presented, and great force was exerted before the head could be extracted. The recovery was less favourable than before.

Mrs. Ryan became pregnant a seventh time, and determined she would not again submit to the induction of premature labour. (See Case XI., first report.)

CASE CXXIII.—On the 23d August, 1836, I again brought on labour in this patient at the seventh-and-a-half month, by perforating the membranes, which was easily done with the stiletted catheter. Labour pains came on in twenty-four hours, and the lower extremities of the child presented, and the child was extracted dead, with the head bruised and flattened. Messrs. Gaskoin and Stutter were present.

CASE CXXIV.—On the 30th August, 1837, Mrs. R. being at the end of the seventh month of pregnancy, I perforated the membranes with great ease, and labour followed the same evening. The feet presented, and the trunk and head of the child were much confused before Mr. William Highmore, who had

the charge of the case on this occasion, could extract the child. The labour pains came on immediately after the membranes were punctured; she recovered favourably.

CASE CXXV.—Mrs. R. again became pregnant about the end of December 1837. "On the 17th of January, the catamenia not having appeared, she began taking the *secale cornutum* for the purpose of producing the expulsion of the ovum. She began by taking gr. xii. four times a day in infusion. This having produced no effect in six days, the dose was increased to gr. xv. four times a day. In six days more this was increased to a scruple four times a day. In six days more this was increased to gr. xxv. without any effect. The dose was then increased to ʒss. four times a day. Mrs. R. then left off the ergot for one week; when she again resumed it she took ʒj. doses four times a day for four days, and this having produced no effect whatever, she left off taking it altogether."

Mrs. R., therefore, took seven ounces of the ergot of rye, which was all procured from Butler's, Covent Garden. As Mr. Highmore procured the ergot, and gave it to her, I have no reason to suppose that the ergot was not taken, as stated, and in greater quantity than I was aware of at the time, or would think prudent to exhibit in other cases. Labour not having followed, I perforated the membrane on the 25th July, 1838, with the stiletted catheter. The pains soon after came on, and the labour was completed in thirty-seven hours. The child was dead, and its head and face were of a dark colour, and much swollen and livid. Dr. Zettwah and Mr. E. H. Hills were present on this occasion.

[To be continued.]

## ON THE DIAGNOSIS OF PERITONITIS.

By ALFRED ASPLAND, Esq.

[For the *London Medical Gazette*.]

THE records of systematic authors will be searched in vain for a detailed account of traumatic peritonitis, and yet its features are striking and peculiar.

Having no standard definition to refer to, the following appears to me accurate:—

Peritonitis, arising from mechanical injury of the membrane itself or of some neighbouring organ.

General inflammation, the result of a wound of the abdomen, is very rare, as it is commonly partial and reparatory: it by no means rarely follows suppuration in the perineum and pelvic operations, even the most trifling, as the passage of the catheter. Here we find active inflammation produced with no contiguity of structure to explain it, apparently the result of communication between the sacral plexus and sympathetic, and by reversing the order of morbid phenomena, we explain what undoubtedly is the fact, that paralysis not unfrequently follows diseases of the bladder and rectum, and succeeds, probably by the same process, the morbid condition of the colon in painter's colic\*.

In two cases of ulcers of the stomach, painful spasms of the muscles of the upper part of the body, and pain down the course of the spine, marked the period of perforation, and continued till death relieved the patient from suffering.

That peritonitis should follow pelvic operations is not wonderful; but it is singular that inflammation of the other serous membranes of the trunk should obtain from the like cause.

I have heard Dr. Addison state that in his experience traumatic peritonitis is almost invariably accompanied by pleuritis; nay more, that the latter lesion is often in marked excess. Such has been the case in all the cadaveric inspections that I have witnessed. Pathological records testify the frequency of disease of the pericardium where permanent stricture of the urethra exists.

To the medical jurist the just appreciation of these lesions, and their relation of cause and effect, is of prime importance; yet they are not recognized by the profession generally. A case in point occurred some months ago in Salop. A woman received some severe blows over the abdomen from her husband. She died on the fifth day; a medical man examined the body, and finding scanty peritonitis and excessive pleuritis, gave it as his opinion that the

unfortunate woman died from natural causes, and not from the effect of the injuries. He allowed that the blows produced the peritonitis, but conceived it too slight to destroy life. To cold he ascribed the pleuritis: acting upon this opinion the jury acquitted the prisoner, and the law was evidently foiled of its victim.

A few cases are on record of idiopathic peritonitis attacking robust persons, and running its course unmarked by the usual and striking symptoms of *pain and vomiting*, but from their rarity they justify the stress which authors lay upon these in the diagnosis of the disease. Such, I venture to suggest, is not the case in the traumatic disease, which is variable in its form, insidious in its course, and very fatal in its termination. I am quite speaking within bounds when I say, that in half the cases of traumatic peritonitis that I have witnessed, diagnosis could only rest upon suspicion; in some the scalpel gave the first intimation of its presence. Old age, debility, the malignant diathesis, and other causes producing cachexia, weakening the vital powers, will explain some of them, but many occurred in persons of robust frame. I fear that many patients have sunk, from the disease being overlooked, who might by timely treatment have been saved.

I select the following cases to illustrate my proposition:—

Jane —, aged 20, of middle stature and healthy appearance, applied for the removal of some warty excrescences from the labia. She stated, and her appearance warranted it, that her habits were temperate, that she had never suffered from syphilis, but that she had been the subject of gonorrhœa for two months.

The warts were removed by the knife in the usual way. I saw her the next day; she was then very ill. The face was pale and anxious; the eyes had a sunken appearance, and were surrounded by a dark areola. Decubitus on the back; legs extended; skin hot, slightly perspirable; tongue dry, red at the tip, furred at the base and in the centre; pulse frequent, jerking, and compressible; sickness incessant; thirst urgent. There was no pain in the abdomen, not even tenderness under strong pressure. The medical attendant regarded it as a case of hysterical vomiting, and was treating it with ether, laudanum, and magnesia. Struck with the peculiarity

\* See Portal's works.

of her expression, I suggested the presence of acute peritonitis, but he appealed to the entire absence of abdominal pain, tenderness, and distension, and continued his treatment. No change occurred till the third day, when the abdomen became the seat of fugitive pain; leeches were now applied, but it was too late, collapse had already commenced, and she sank in twenty-four hours. A section of the abdomen displayed slight lymph deposit and seropurulent effusion, coating the whole extent of the peritoneum.

Alice Jackson, æt. 40, admitted March 25. Her history ran thus:—Up to the period of her attack she had been strong and active; she had noticed a tumor in the left groin, for 6 or 7 years, but had never experienced inconvenience from it till the 23d March, when vomiting and epigastric oppression first announced strangulation. On examination a flaccid tumor was found protruding from the saphenous opening, part of which was easily and immediately reduced. The abdomen was natural; there was no tension or pain, even during active manipulation. Countenance pale and anxious, tongue red and dry; thirst distressing. An enema produced evacuations. Mr. — now saw the patient, and though the countenance evinced increasing distress, he determined to defer the operation, influenced by the following circumstances:—The impossibility of peritonitis existing in the total absence of pain, tenderness, or tension; the fact that the bowels had been twice relieved during the short time that she had been in the hospital.

In the evening she had another motion, but the vomiting continued unabated, and the ejected matter had a strong feculent odour. Still there was not the slightest pain or discoloration of the tumor.

On the morning of the 26th the sickness was constant, and the countenance anxious in the extreme. Mr. — now operated. A portion of the small intestine was strangulated, of dark colour, but smooth and even surface; it was returned into the abdomen, and the operator, considering the absence of pain, and the relief of the bowels, unhesitatingly gave a favourable prognosis. She died eight hours afterwards; and the presence of numerous adhe-

sions, and a pint of bloody serum in the abdominal cavity, left no room for doubt as to the existence of peritonitis in its most acute form.

In the above cases sickness was urgent during the whole course of the inflammation; but there are few practitioners, probably, who cannot recall one or more cases where it was either very slight, or altogether absent. If, then, the two most salient points in the diagnosis of peritonitis do not necessarily belong to it, it will be asked, what pathognomonic sign there is? The answer will be, examine the expression of the face. Here we shall rarely be at fault. Nature points to the countenance—to the pallor—intensely anxious expression of the mouth and eye—to the sunken appearance of the latter—to the darkened areola round it—to the expansion of the alæ of the nose during inspiration, more marked than normal, not sufficiently so for acute thoracic disease; to these she points with almost unerring certainty in the diagnosis of peritonitis.

Every one acquainted with the elements of our profession is aware that an overlooked peritonitis is, in nine cases out of ten, fatal, and Mr. —'s case shows the prime practical importance of not waiting, where strangulation of the bowels exist, till abdominal pain is established, but of repeatedly examining the expression of the face. It is not unreasonable to suppose that had a correct diagnosis led, in the above cases, to appropriate treatment, that both their lives might have been saved.

Ashton-under-Lyne,  
Sept. 1839.

## SMALL-POX AND VACCINATION IN NEWARK.

*To the Editor of the Medical Gazette.*

SIR,

I HAVE been led, in the course of my daily duties, to believe that a permanent record of the state of any population with respect to small-pox and vaccination for any given period (as for the year 1839, for instance), would answer several important ends. Among others, such a census would serve as a standard of comparison, both as regards time and place; and it might prove a useful stimulus in favour of, I am almost ready

to say, an expiring blessing, by revealing the low ebb to which in these districts vaccination is unfortunately fallen. I respectfully beg your acceptance of a record of this nature for the East Ward of the borough of Newark in the county of Nottingham.

Newark contains at this date from 10,500 to 11,000 souls, and is situated on a navigable arm of the river Trent, near the foot of an eminence, broad and of no great height, called Beacon Hill, which is surrounded by rich levels of great extent, frequently flooded by the Trent and Witham. One third of the town lies low, on a damp black loam; while the other and larger portion is raised from twenty to thirty feet above the surface of the river, and stands on gravel and fine sand.

Newark is healthy; but its atmosphere is moist and relaxing.

Assuredly there is not here the amount of privation of the necessities of life that we find in other places. The houses in which a visitor perceives decided marks of continued destitution are only (in this ward) from four to five per cent. of the whole according to my experience this summer; and in many in-

stances I am aware that the fault lies in the individuals themselves.

Within the last fifteen years the inhabitants of this county have made great advances in the comforts of life, more particularly in their houses, clothing, and personal cleanliness. The result is, that I have found much less struma and feebleness of frame in Newark than I expected; and not much active disease of any kind.

This borough is divided for municipal purposes into three wards, nearly equal in population. Their size, compactness, and notoriety as to boundaries, &c. make these civic divisions very manageable in statistical investigations. My engagements not permitting me to embrace the whole town, I confined my inquiries on the subject under consideration to the ward in which my house is placed.

As it would occupy by far too many of your pages were I to request you to insert the original tables containing a great number of particulars respecting 3406 individuals, I shall proceed to give in a short table a numerical summary of the information collected.

Name.	Present Age.	Inoculated.				Vaccinated.				Casual Sm. P.			Remarks.	
		Age when	Mark.			Age when	Mark.			Age when	After			
			P.	I.	N.		P.	I.	N.		Inoc.	Vac.		nei- ther
Luke Brown .....	53	3	1	...	...	...	...	...	...	...	...	...	Severely pitted in face. Mark superficial. Small Pox mild.	
Mary Jones .....	3	...	...	...	...	...	1	...	...	...	...	...		
Edward Dodd .....	79	...	...	...	...	...	...	...	5	...	...	1		
Hannah Tebb .....	28	...	...	...	1	1	...	...	3	...	1	...	Unprotected.	
Thomas Sims .....	3	...	...	...	...	...	...	...	...	...	...	...		

First, we have here the name of the person, and his or her age: then follows a column for the age of the individual when he was inoculated, together with others, wherein to indicate the state of the mark on the arm, whether perfect,

imperfect, or not visible. Vaccination is similarly provided for; as well as casual small-pox, whether after inoculation, vaccination or after, neither of these diseases. A large space is left for remarks.

*A Tabular View of the number of Persons who have passed through the Small-Pox and Cow-Pox, or who have had neither disease, in the East Ward of Newark-upon-Trent, for the year 1839.*

Population of East Ward in 1839.	Inoculated.				Had Small Pox casually.				Vaccinated.				The unprotected.	Total of Persons examined.
	State of Mark				After.				State of Mark					
	Perf.	Imp.	None.	Total.	Inoc.	Vac.	Nei- ther.	Total.	Perf.	Imp.	None.	Total.		
3454	893	171	36	1100	8	55	791	854	878	186	33	1097	355	3406

On comparing the great total examined, with the real number of the population (as nearly as I could learn), forty-eight will be found unnoticed. These I have been unable to reach for various ordinary reasons.

The details which are not to be compressed into a short table, I shall now endeavour to preserve, arranging them under four natural heads, according as they refer to inoculated and casual small-pox, to vaccination, and to the unprotected portion of the population.

*Inoculation.*—It is not to the credit of an enlightened community that after thirty-eight years' diligent promulgation of Dr. Jenner's inestimable discovery nearly two-thirds of a municipal ward in a respectable town on the great North Road should have passed through the small-pox, and that 1100 should have submitted to this loathsome disease advisedly\*. The vast majority of these last were inoculated in their infancy or early childhood.

Only thirty-three were older than ten years; and only one more than twenty years of age.

Fifteen only out of the 1100 have been much pitted, or one in seventy-three; but of these ten were so severely marked, that not a point of natural skin remained in the face. I took no note of the cases where the pits were only few in number.

With respect to the mark or scar upon the arm left by inoculation, I pronounced 893 to be perfect, 171 (16 per cent) imperfect, and in 36 persons (3½ per cent) it was altogether wanting.

As far as I am aware we have at present but a very brief description of the mark after inoculation. It is only said, by Rayer and others, to be a large and deep cicatrix like that produced by cauterization. This is true as far as it goes; but it should be added, that it is circular or oval, and that, when of some standing, it is hard, and traversed by a very varying number of sharp ridges, often short and confused, but more frequently converging from the circumference to the centre of the mark. It is to be stated also that depressions, pits, or foveæ, are very common, and which are not to be distinguished from those observed in the scar after vaccination. In

a young female, who had small-pox in this ward after *inoculation*, they were both numerous and distinct.

Wherever I found the cicatrices from one-third to three-fourths of an inch in diameter, or even an inch occasionally, and possessing a fair portion of the above mentioned characters, I considered them perfect; and this the more readily, as I found that they had been protective.

The marks which I took to be imperfect were the very superficial, the smooth superficial, the very irregular in shape (from excess of inflammation), the small and smooth, the very small, and very large. I have seen a circular mark, two inches in diameter, perfect, except as to size.

The inoculated mark is very lasting. It is to be seen in full force on the arms of some octogenarians, after having been placed there in their childhood; but on the whole, the lapse of years has a tendency to make it smooth and superficial.

I have thought it worth while to give rough sketches of the natural size of marks not seldom met with, and yet perhaps little known, save to the few who attend particularly to the diseases of the skin. It is most probable that they are protective.

Number 1 is often seen in young people. No. 2 is quite the same as a cicatrix, which will be found figured as No. 3, among the vaccine marks. Numerous short striae issue from the circumference of a smooth white disc.

I saw No. 3 five times after inoculation, and four times after vaccination. It is a circular cicatrix, shallow, and glazed, with 14 to 18 foveæ studding the circumference in a ring.

No. 4 is to be remarked for its size and shape, but more especially for the accuracy with which it is divided into halves; the lower half being filled with radiating striae, while the upper is white, smooth, and shining.

No. 5 is an example of a cicatrix with broken and disturbed ridges.

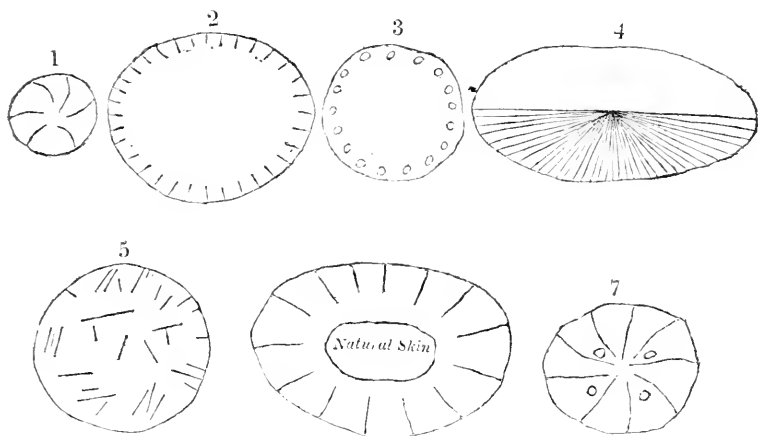

No. 6 is curious for the oval space in its centre of perfectly sound skin, standing on a glazed surface traversed by 14 striae.

No. 7 is often met with.

I have included 35 persons among the number of those who have been inoculated, although no marks appear, because they clearly remembered the operation and its subsequent indisposition, or be-

\* A distressing event took place in this town some years ago: an inoculated child infected its mother: the mother died, and left behind her six young children.

cause there were marks elsewhere on the body.

### *The Casual or Natural Small-Pox.*

We find the number of persons in this ward, who have had this disease by casual infection, to be 854, or one quarter of all the persons examined—a proportion whose magnitude is much to be regretted.

Fifty-five of these had been previously vaccinated, and eight had been inoculated.

The following little table shews that more than one-half of the 854 underwent

the disease between the ages of three and ten years; and it further tells us how rare casual small-pox is at the extremes of life; and this for obvious reasons. It appeared, four years ago, in a man now sixty nine-years of age, in so severe a form, that he remains to this day a very emaciated object.

Forty-seven more females than males have been attacked casually,—a circumstance for which I cannot account.

In casual small-pox I found 16 per cent. much marked in the face (indicative of a severe disease), instead of  $1\frac{1}{4}$  per cent. as in inoculated variola. The actual number in this ward thus disfigured by *natural* small-pox is 132. Of these again in 94 the features are wholly covered with marks, and often seamed.—(71 per cent.)

This number, 94, is composed of fifty-seven males and thirty-seven females, giving a proportion of nearly three males to two females; so that sex seems to have had some influence.

These disfigurements do not seem confined to any one complexion or temperament. There is no doubt, however, but that struma now and then caused other very serious sequelæ, especially as regards hearing and sight. Two females and one male have had the small-pox casually twice. They are persons of credibility; and I believe the satisfactory accounts they give of themselves.

Two females were born full of the pustules of small-pox; and in one of both sexes the eruption appeared two days after birth.

Eight cases have occurred of variola

after inoculation—six of them in females. In five of the eight, the marks on the arm were imperfect, and in the remaining three none whatever were to be seen. Thomas Roberts, one of the sufferers, was two years old when inoculated, and caught the disease in the natural way in his 56th year. In the other instances the interval was much shorter; as 1, 2, 6, and in a person now 60, 15 years. The disease was in most cases severe.

The proportion of the vaccinated who are afterwards affected by small-pox in a well-marked form is a point of great importance; indeed, upon this must ultimately depend the fate of vaccination.

Fifty-five persons have had variola after vaccination, or  $5\frac{1}{2}$  per cent. of the whole vaccinated; and the secondary disease was severe in 11 per cent.

Dr. Gregory (Med. Chir. Trans. xii. 336) says that there is a remarkable connection between the degree of perfection in the vaccine cicatrix, and the violence of the secondary disease; but this did not hold good at Newark; some of the worst cases had remarkably good scars. Of our 55, 15 had imperfect marks—an unusual large proportion; and in three there were none whatever; but in these I had sufficient evidence of the operation and of the accompanying fever.

The per centage of small-pox after vaccination here given nearly agrees with that stated by Mr. Robertson in his able pamphlet recently published; and with the results derived by Mr.

Field from ten years' experience in Christ's Hospital.

Mr. Cross of Norwich rates it as from two to five, and the records of the Brighton Lying-in Institution at 9 per cent.; but Dr. Gregory has shown that during occasional epidemics it may rise far higher.

All the cases have occurred in young persons, mostly below eleven years of age; and the same is pretty true with small-pox after inoculation.

Puberty seems to have had little to do in the matter, as the following table will show.

*Ages of persons when attacked by small-pox after vaccination.*

The person left out of this table was ignorant of the date of her attack.

The intervals between vaccination and secondary small-pox are very loose and scattered, as we see here exhibited. Five persons had each an interval of five years, five others of seven, and so on.

54—Total persons.							

Dr. John Thompson, of Edinburgh, in his researches on the varioloid, noticed the same irregularity. The eruption he found to occur at various intervals, from a few days to 15 years; not warranting the suspicion, that the preventing or modifying power of the

cow-pox was weakened or exhausted by time.

Of Dr. Gibson's 251 cases of modified small-pox (Edin. Med. Surg. Journ.) it appears that by far the greater number were those vaccinated less than two years before.

On my first seeing these 55 cases of secondary variola, I neglected to inquire into the state of their health at the period of vaccination; but on revisiting seventeen of them in succession for this purpose, I found that they were well at the time, had no disease of the skin, and that the progress of the vesicle had been satisfactory. In one, however, the vesicle had been much disturbed to procure lymph. Whether in all these cases the lymph itself was good cannot now be ascertained.

As has repeatedly occurred before, I found the vaccinated children of the same parents very apt to take on the modified small-pox. This took place in seven families with us.

A young lady, who resides in this ward, is an uncommon example of variolous idiosyncrasy. She was carefully vaccinated when three-quarters of a year old, and the cicatrix is still good, as I am informed. At five years of age she had a well-marked attack of small-pox, as identified by several competent observers. When of the age of fifteen she had another attack, mild, but distinct, also recognized as variola by many medical men. At the age of twenty-three, while at Brighton, this young lady had the disease a third time, and in a confluent form, which, however, passed away without leaving any but slight marks on the face.

The daughter of Dr. Stewart, late of Plymouth, was vaccinated in her infancy, and bore evidence of the disease having gone through its regular stages. In about three years she had the natural small-pox, and after an interval of several years, the same disease attacked her again in a very severe degree (*Med. Repos.* iii. p. 38.)

Dr. Jenner knew a Mrs. Gwinnett, of Cheltenham, who had the small-pox five times (*Baron's Life of Jenner.*)

**VACCINATION**—It is certainly to be lamented that the number of persons found to be vaccinated in this ward is less than that of the inoculated, although the difference is very small.

Two males and one female were inoculated direct from the cow. Of the former, a boy was thus protected at Tewksbury, and a man, twenty-three years ago, by an army-surgeon at Barnaby, near Brigg in Lincolnshire. The woman was vaccinated, in Devonshire, by a Mr. Sims, more than forty years ago. From her three of the surgeon's children were infected, and so on through the neighbourhood.

1997 persons have been vaccinated in this municipal division. As in variola, the proportion of the imperfect mark to the perfect is 16 per cent.; and three per cent. of the whole have no mark. Two of the imperfect marks were tested successfully by inoculation. The pustule produced ran a short and blighted course. This mode of trial is very rare in England.

I do not think the proportion just mentioned large, considering the difficulty under which vaccinators labor of watching the nature and progress of the vesicle. Its apparent simplicity will, I fear, be fatal to Jenner's discovery.

The vaccine mark or scar, when in its pure form, I have found just as described by Willan long ago, and more minutely since by Dr. G. Gregory. Dr. Gregory says that it is distinct, circular, radiated, and cellulated (*M.-C. Trans.* xii. 337.) Rayer very aptly calls it "a gouffred cicatrix."

In judging of its imperfection, I was guided by much the same rules as those adopted in judging of the inoculated mark.

I have here sketched four outlines of the vaccine cicatrix of somewhat common appearance. Among other things they shew the diversity prevailing in the number of the striae.

Dr. Geo. Gregory, in one of his definitions of a perfect cicatrix, limits the

number of cells to six or eight, but I have more frequently found double and

treble that number. They disappear, I think, in the course of time, are numerous at first, and then become obliterated.

The pits (perhaps representing cells) are often disposed concentrically in double or single rows, and they observe, quite as often, no discernible order.

The vaccine marks differ principally from the variolous in greater delicacy of structure generally; they are less rugged, hard, and deep, and are more abundant in foveæ. In one case, I noticed that a hair arose from the bottom of every one of nine foveæ. Many think that these pits have no connexion with the cells of the vesicle, but are mere depressions in the denuded corion; for they appear occasionally, as I well know, in the cicatrices of burns and scalds; but I have seen these depressions well marked, when, from the remarkable superficiality of the sear, the corion must have suffered little or nothing.

By far the greater number of persons are vaccinated before the end of their first year: thus, out of 1097, there are but sixty-nine who were vaccinated after their fifth year, and only nine after their twelfth.

If it be true—and the notion is now very prevalent, that the protective power of vaccination wears out after an uncertain term of years, it follows as a natural, undeniable, and most serious inference, that by far the greater portion of those who imagine themselves under

its benignant influence, are in truth open to the attacks of variola.

This opinion is mainly supported by evidence from Germany, and it is assented to by English practitioners, reasoning from more limited observations; but seeing the numerous centres of infection created daily without bad consequences in and about Newark by inoculators, and by wayfaring families, I cannot at present but imagine that the efficacy of vaccination is more durable than is supposed. We have had in all Newark only eight deaths from small-pox in 25 months—and this has been about the average for 12 years past.

Re-vaccination is recommended every seven or ten years. Only let the public think this necessary, and cow-pox will soon be obsolete. As it is, I found the other day in the village of Thorpe,  $3\frac{1}{2}$  miles from this place, that out of 45 persons (examined by Houserow) 43 had had the small-pox naturally or artificially, and that only two had been vaccinated.

But if, indeed, all persons are liable to variola at the end of the tenth year after vaccination, as is supposed, then 614 of our vaccinated population are now defenceless, as we learn from the following table, in which are arranged, in eight periods, of 5 years each, the intervals since the inhabitants of this ward were vaccinated.

*Table of Intervals since Vaccination.*

Sex.	From 1 day to 5 years.	From 5 to 10	From 10 to 15	From 15 to 20	From 20 to 25	From 25 to 30	From 30 to 35	From 35 to 40	Total.
Male, . . .	113	97	100	60	35	31	36	14	486
Female, . .	125	89	82	78	62	55	46	15	553
Total, . .	239	186	182	138	97	86	82	29	1039*

Vaccination is principally employed by the upper ranks among us, although even among them there is reason to fear that its value is undergoing depreciation. It is not unexampled to find one of these families begin with vaccination, and then, on the occurrence of some single untoward event, they inoculate all the younger children.

The unprotected, that is, those persons who have neither passed through cow-

pox nor small-pox, are numerous. The chief causes of this are, the absence of any pressing and immediate occasion for protection, the growing indifference to vaccination, and among the poor, the great expense of inoculation\*. One respectable female, aged 85 years, has through life refused protection artificially, from ill grounded religious notions, as was often observed during the first introduction both of inoculation and vaccination. Nevertheless, no one

\* Those who have had secondary small-pox are excluded, as well as a few who did not know when they were vaccinated.

\* This is from 4s. to 4s. 6d. for each child among the non-medical inoculators.

is too old to die of the small-pox. At one of the friendly tea-meetings of the Medical Society of Geneva, to which I had in 1833 the honor of being invited, M. Decandolle, the distinguished Professor of Botany, related a striking anecdote in connexion with this point.

He said, that when vaccination was new, he was present at a meeting of the Institute of France, to receive a report on the subject. The report was accordingly read; much was said in admiration of the discovery: some of the members were to be vaccinated, and all were to be vaccinators. On the next chair to M. Decandolle sat a very aged duke of dignified appearance. He too had a word or two to say; it was all, in his opinion, very excellent, but he had gone on prosperously enough for 84 years, without troubling Dr. Jenner, and he should crave leave to continue so to do.

That day month M. Decandolle attended another meeting of this scientific body, and observed that the seat of his high-bred and well-satisfied neighbour was vacant. He inquired for him—he was dead of the small-pox!

Four persons, of both sexes, in this ward, have times without number resisted the natural small-pox. Three are now past middle life; and one has slept in the same bed with his child full of the eruption.

Twelve, of various ages and sexes, have resisted inoculation many times each; and, in eleven other individuals, the same has taken place with vaccination.

I have been at the trouble of arranging the present ages of the unprotected portion of our population of 3454 souls into the following table. It is not destitute of interest, and brings, within the influence of *number*, facts only known hitherto in the general.

Five-sixths of the whole are under eleven years old: the older persons belonging, without exception, to the working classes.

From the above facts the following conclusions may perhaps be drawn:—

The community is not sufficiently aware of the very great value of vaccination, less than one-third having availed themselves of its preservative power. This is a result of my inquiries for which I was unprepared; and for which an immediate remedy should be provided.

Ages of the unprotected.	Male	Fem.	Tot.
From birth to $\frac{1}{2}$ year old	14	19	33
„ $\frac{1}{2}$ to 1 year old ...	37	40	77

„ 65 to 75 .....	1	2	3
„ 75 to 85 .....	0	3	3
Total .....	166	179	345*

Vaccination appears to be entitled to all that qualified, but warm, approbation which for ten years it has enjoyed; but judging from experience in this ward, inoculation is very much the better guarantee for the individual. So fully impressed are the majority of our population with the superior security afforded by inoculation, and so jealous are they of interference with the management of their children, that, in my humble opinion, the legislature cannot add beneficially to the penal enactments already in force with respect to small pox, except perhaps by rendering it imperative for unprofessional persons to take out a licence to inoculate, bearing a stamp of a certain value.

It is not in the power of the medical practitioners to put an end to inoculation. If they should refuse to perform this operation, a sufficient number of uneducated inoculators would start up immediately, and find good remuneration, as is the case in and about Newark at this moment.

Vaccine institutions should be again placed in activity, in the large towns having salaried vaccinators at convenient out-stations. Poor-law unions should encourage vaccination by giving their surgeons 1s. 6d. for each person satisfactorily protected.

Information should be distributed through the towns and villages, from the pulpit and by popular tracts, renewed every two years.

No servant should be hired unless he or she can shew marks of having un-

\* This is ten below the real number: where the error lies I cannot now discover.

dergone cow-pox or small-pox. The same caution should be observed before admitting any person into a Sunday or national school, into any dock yard, or public establishment of whatever kind. The inmates of houses of industry, of correction, or jails, should be protected also as soon as possible.

Were these measures persevered in for five years, vaccination would assume its rightful position, and the small-pox be all but extirpated.

J. J. BIGSBY, M.D.

Senior Physician to the Dispensary.

Newark upon Trent,  
Aug. 29, 1839.

#### ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

*Medical and Physiological Problems; being chiefly researches for correct principles of treatment in disputed points of medical practice.* By WILLIAM GRIFFIN, M.D., and by DANIEL GRIFFIN, M.D. Part I. Limerick, 1839. 8vo. pp. 114.

THE following problems are discussed in the work before us:—

1. What principles should be kept in view in the treatment of enteritis?

2. How are nervous affections distinguishable from inflammatory?

3. Under what circumstances and to what extent is bleeding proper in diseases of the brain?

4. On what morbid state does the occurrence of coma and sudden death in jaundice depend?

5. Is the law of visible direction, as at present received, a true one?

6. Is laryngismus stridulus, or the crowing disease, a spasmodic or paralytic affection?

These essays are replete with instruction, particularly the first three. The great lesson taught by the discussion of the first problem is the benefit derived from opium in inflammation of the bowels; and the conclusions with which the paper terminates are as follows:—

"General experience testifies, that the strongest purgatives will not operate in the early stages of inflamed bowels unless large depletion by the lancet has been premised, that is, unless the violence of the inflammation has been

in some measure subdued; while, on the other hand, as soon as this has been accomplished, they commonly occur spontaneously, or with the assistance of the mildest purgatives.

Notwithstanding the free operation of purgatives at an early stage of enteritis, the inflammation may proceed to a fatal termination, unless arrested by other remedies.

A purgative has been known to occasion inflammation of the bowels, and when inflammation has been subdued by other remedies, it has brought on a recurrence of it.

Inflammation of the bowels may be perfectly subdued without any evacuation at all.

The bowels may even sometimes continue in a confined state for three or four days after the inflammation has subsided, without occasioning injurious distension."

Nervous affections are to be distinguished from inflammatory ones, according to Dr. W. Griffin, by the spinal tenderness which accompanies the former; for "in all acute inflammations of vital organs, I believe that no spinal tenderness will be found, except where it existed previous to the supervention of the attack\*, or where the spinal cord itself happens to be the seat of such inflammation. In all neuralgic affections, on the contrary, tenderness of some portion of the spinal column, *usually that corresponding to the affected organ*, may be detected, except in some rare cases, in which, it seems probable, the ganglionic nerves alone are concerned. As these cases must still present a difficulty in their diagnosis, we must rest contented with those general characteristics, which, however vague or liable to lead us into error, are all we have to guide us, and all we have hitherto had to determine our opinion in that large class of neuralgic affections, for the detection of which I have here been offering a new, and I believe less doubtful, sign."

He thinks that these observations will apply with almost equal truth to those nervous affections which resemble chronic diseases, such as pains in the chest, with cough and oppression, leading to apprehensions of phthisis, &c. &c.

\* "Some writers on spinal irritation state, that they have found spinal tenderness with inflammation of liver."

In the third essay the author opposes the common plan of treating apoplexy with indiscriminately large bleedings, and is of opinion that they are hurtful in all cerebral cases where there is extensive disease of the brain, by interfering with the process of reparation; or where the disease of the brain has been attended with severe and protracted pain, on account of the exhaustion which follows it. As an illustration of this, he quotes the case of a man, aged 40, who had been suffering intense pain in the head, without advice until the fifth day, when twelve ounces of blood were taken from the temporal artery, his head was shaved, and a kettle of cold water poured over the crown and occiput; but in a few minutes the patient expired. Was death hastened in this instance by the treatment?

We do not quote from these well-written essays so largely as we should otherwise do, on account of their having already appeared in the medical journals, some of them, indeed, in the *MEDICAL GAZETTE*. While they are a manifest proof of the professional tact and earnestness of the Drs. Griffin, they may be added to the numerous proofs that the old rigour of the antiphlogistic system is much relaxed—that medicine, in fact, is less bloodthirsty in 1839 than it was in 1825. These Problems will be read with profit by practitioners of every class: we trust that we shall soon be favoured with a second part.

—

*On Granular Degeneration of the Kidnies, and its Connection with Dropsy, Inflammations, and other Diseases.* By ROBERT CHRISTISON, M.D. F.R.S.E. President of the Royal College of Physicians of Edinburgh, &c. Edinburgh and London, 1839. 8vo. pp. 288.

THIS is a treatise on the disease now known throughout Europe by the name of Dr. Bright. It is divided into six sections, besides an appendix of illustrative cases with remarks.

The first section treats of the pathology and morbid appearances of this disease, which is divided into three stages—the incipient, the middle, and the advanced—distinguished by their organic alterations.

In the second section the author considers the symptoms and history. The following passage on the best method of testing albuminous urine will be acceptable to many of our readers.

“The presence of albumen in such cases may be detected by various chemical tests, such as heat, nitric acid, corrosive sublimate, and ferrocyanate of potash; all of which separate a flaky precipitate. But the most convenient and most conclusive are the first two, namely, heat and nitric acid; and as the present observations are intended mainly for practical purposes, it seems unadvisable to press the reader by discussing the chemical merits of any others. At a temperature a little above 160° F. the urine of this disease in its early stage in all circumstances, and generally too in its advanced stages becomes turbid; and complete coagulation of the albumen gradually takes place as the heat rises to ebullition. If there is any deposit of lithic acid or lithate of ammonia, this in the first instance is dissolved, and the urine becomes clear. Muddiness from other causes, more especially from modified mucus, is not thus dissolved, however; and hence, where the muddiness is considerable, it is often well to filter the fluid before testing it. When the temperature has been raised to the boiling point, the urine sometimes forms a gelatinous mass; more frequently it becomes a soft pulp, like thin custard; often too, where the quantity of albumen is less, there are distinct flakes in a supernatant and separate fluid\*. The earlier the

---

\* The best way of operating is with a tube about a third of an inch in diameter. A spoon, which many use, is a clumsy substitute, which will not show the nicer degrees of coagulability.

I may take this opportunity of observing, that it would singularly promote the future study of the disease were physicians to employ some common nomenclature for the different degrees of coagulability. Important scientific and practical conclusions might then be drawn, which at present are unattainable. I venture to propose the following as well-defined, and in practice convenient. 1. *Gelatinous by heat*. 2. *Very strongly coagulable*, where a precipitate distinctly separates by heat, and yet occupies in twenty-four hours the whole, or nearly the whole, fluid. 3. *Strongly coagulable*, where the precipitate in twenty-four hours occupies half the volume of the fluid. 4. *Moderately coagulable*, where it occupies a fourth of the fluid. 5. *Slightly coagulable*, where it occupies an eighth of the fluid. 6. *Feebly coagulable*, where it occupies less than an eighth of the fluid. 7. *Ilazy by heat*, where the urine becomes cloudy, but does not form visible flakes a few seconds after being boiled. In appre-

stage of the disease, the more is the urine loaded with these flakes, and the more does it tend to form a pulpy or gelatinous mass. Nitric acid acts in like manner; but it separates the albumen always in the form of flakes or pulp.

It is advisable to make use always of both tests; and this for several reasons. For first, if the urine is ammoniacal, the action of heat may be prevented even where the proportion of albumen is great. Secondly, heat alone may occasion a flaky precipitate where there is no albumen, owing to the superabundance and consequent separation of earthy phosphates,—a deposition which nitric acid will both prevent and remove. And thirdly, nitric acid alone may occasion a flaky precipitate of lithic acid; which however is resolved by an elevation of temperature, while albumen remains insoluble. In regard to these sources of fallacy, I have to observe in the first place, that the urine should be always tested if possible before it decays and becomes ammoniacal; because I have found that sometimes even nitric acid added in excess did not separate albumen which had been present in large quantity,—a fact which is probably to be ascribed to the albumen having itself undergone more or less decay along with the other principles of the urine. And secondly, as to the fallacy arising from the separation of earthy phosphates by heat which was first fully and ingeniously established by Mr. Rees,—this is a fallacy rather in the advanced stage of the disease than at the early period, with the symptoms of which we are at present occupied; for the separation of flakes of the earthy phosphates is never considerable, and cannot easily be confounded with the great mass of flaky coagulum or pulp occasioned by the presence of albumen.

The third section is on the secondary diseases which are of most frequent occurrence in combination with granular disease of the kidneys; these are, “Dropsy, diarrhoea, pleurisy, and peritonitis, pneumonia, catarrh, dyspepsia, and chronic vomiting, coma with other affections of the head, chronic rheumatism, organic diseases of the heart, and organic diseases of the liver.”—(P. 76.)

Of these the first is the most frequent.

Dr. Christison states that, in his experience, the proportion of dropsies partly or wholly depending on organic disease of the kidneys, is in Edinburgh three-fourths; and at Strasburgh, according to Professor Forget, it is about one-half. Dyspepsia, however, is almost as frequent; and diarrhoea is very common at Edinburgh, though “comparatively a rare secondary affection in other cities where the habits of granular disease of the kidneys have been under the subject of attentive observation.”—(P. 89.)

The fourth section discusses the causes of the disorder. Among the chief of these are exposure to cold and wet, and spirit-drinking, especially when practised by persons of a serofulous constitution. Scarlatina, too, is a predisposing and perhaps even an exciting cause.

The prognosis in granular disease of the kidneys is treated of in the fifth section. It is influenced in a great measure by the probability of the patient's recovery from the secondary diseases above mentioned. Another important rule is that the patient's life depends on the exertion of a sufficient quantity of solid matter in the urine, as is explained in the following passage:—

“The patient's danger is on the whole in proportion to the lowness of the density of the urine; and the reason obviously is, that the lower the density of the urine, the farther has the organic alteration in the structure of the kidney advanced in its progress. This rule, however, applies only where the quantity of the urine is not materially greater than the natural average. On the other hand, it applies with peculiar force where such urine is also defective in quantity. For example, the patient may always be considered in imminent danger where the urine has a density of 1008 or 1010, and its quantity does not exceed twelve ounces daily.

“In reference to this article of the prognosis, it would perhaps be preferable that physicians were to look less to the mere density and quantity of the urine abstractedly, and more to these qualities as constituting a measure of the amount of daily solids excreted. It is the diminution in the daily discharge of solids with the urine that constitutes essentially the unfavourable prognostic. Nature allows of a considerable variety in respect of the discharge of solids in the urine without the health being neces-

ciating the last degree of impregnation, it is convenient to heat only the upper half of the fluid in the tube.

sarily affected. This may be remarked on studying the condition of the urine both in different individuals and in the same individual at different times. The history of the present disease shows that a very extraordinary diminution from the natural standard may take place for a great length of time, without at all events any immediate or very obvious risk of life. We see patients frequently living for many weeks in the comfortable enjoyment of tolerable health, though the amount of solid excretion by urine is diminished to fully one-third of the natural daily discharge. Seldom, however, does the quantity fall to one-fourth without troublesome secondary disorders forming; and any material reduction under that amount is speedily followed by urgent symptoms, most generally by drowsiness, leading on to stupor and coma."

Section 6th is on the treatment.

General blood-letting is indispensable in the early stage of the majority of cases; counter-irritants to the loins are advisable after general or local depletion has been pushed to the requisite extent. Warm clothing is especially necessary. Diaphoretics are useful, yet not quite so advantageous as Dr. Osborne alleges. Purgatives are commonly necessary, but must be used with caution, lest diarrhœa should be brought on, which is a troublesome secondary affection; yet in dropsy, or when coma threatens, this fear must often be disregarded. Diuretics are rather to be abstained from in the early stage of the disease; but in some of the secondary affections no other remedies are so promptly efficacious. Mercury is useless and dangerous in the primary disease; "yet there seems no sufficient reason for carrying the prohibition of mercury so far as to exclude its use in small doses for aiding the action of other remedies, such as diuretics and cathartics" (p. 141.)

We confess that we think it better in so critical a condition to abstain from so dangerous an ally.

Among the remedies for the secondary diseases we will only mention creosote, strongly recommended by our authors for the chronic vomiting, and acetate of lead for the diarrhœa, when obstinate. The creosote is to be given in the dose of one or two drops, twice, thrice, or oftener, in the 24 hours; and the acetate of lead in the dose of three grains with

half a grain or a grain of opium, three, four, or six times a day.

"In urgent cases it is often very useful to unite with this practice the employment of an anodyne suppository of three or four grains of opium once or twice in the twenty-four hours; and sometimes, where all these means failed, I have seen an occasional injection of ten or fifteen grains of acetate of lead in three ounces of water prove serviceable."

The illustrative cases, thirty-one in number, are narrated with Dr. Christison's usual clearness, and, like the rest of the work, are highly instructive. We strongly recommend this book to our readers.

---

*The New York Journal of Medicine and Surgery.* Published Quarterly. No. I. July 1839. New York. 8vo. pp. 244.

THE first number of the new journal before us contains seven original articles on the following subjects:—

A summary view of the progress of medicine in America, by Dr. Watson; a case of bony tumor arising from the pelvis, by Dr. Rodgers; cases of sensitive tumors of the female urethra, by Dr. Hosack; an essay on cancer of the uterus, by Dr. Swett; observations on morbus coxarius, by Dr. Adams; a case of abstraction of the uterus after delivery, reported by Dr. Griscom; and an account of extirpation of part of a rib for neuralgia, by E. H. Dixon.

The bony tumor, which weighed fourteen pounds, was removed by operation, and the patient, as might have been expected, died twenty-two hours afterwards. The dangers attending and following such an operation were fairly stated to the patient, who deliberately made up his mind to its performance after consultation with his friends; but we think that more should have been done—he ought to have been dissuaded from it.

In the cases of tumors of the female urethra—one occurring in the practice of Dr. Hosack, and the other to Dr. Mott—a cure was effected; in the former instance by dissecting out part of the urethra, and in the latter by removing the meatus urinarius only.

The case which Dr. Griscom calls "abstraction of the uterus after delivery," though unfortunately not quite

unparalleled, is yet very extraordinary. He says—

“On the 7th of April, 1839, at the request of Ira B. Wheeler, Esq., coroner, I examined the body of Mrs. Cozzins, the wife of a respectable mechanic, No. 328, Madison Street, at the time absent from the city. I was assisted in the examination by Dr. S. C. Ellis, in the presence of Drs. Nichols, Lobstein, and Walters. Before the examination we obtained the following history:—Mrs. C. was delivered of a healthy, living child, about one A.M., without any other assistance than her sister and a female friend, both married, and the former a mother. The cord was tied, and cut *secundum artem*; but the placenta was retained beyond the usual time. Three hours having elapsed without its disengagement, the sister went for a physician, and obtained the services of Septimus Hunter, who represented himself to be a physician, but was at the time a clerk in a drug store. Upon his arrival he immediately addressed himself to the task of removing the placenta, the successive stages of which operation will be mentioned presently.

“We were shown, prior to the dissection, a mass of fleshy substance in a wash-bowl, which I at once recognised as a uterus; also, in another vessel, the placenta was shown us, which was entire, but without a vestige of the umbilical cord attached to it. The latter was subsequently discovered in a pail of dirty water.

“On stripping the body, the abdomen was found very sunken. The usual incisions were made, and the following uncommon appearances were presented:—1st. A total absence of the uterus. 2d. The broad ligaments much torn and ragged, and partly deficient. One fallopian tube was absent, but both ovaria remained *in situ*. 3d. The upper extremity of the vagina was open and free, so that the hand introduced from without would pass directly into the cavity of the abdomen, and the intestines could be touched. The intestines were high up, as left by the contracting uterus. 4th. A considerable quantity of extravasated blood was seen on each side near the ovaria, forming spots of ecchymosis beneath the membranes. No effused blood was seen, however, within the abdomen, except this. 5th,

a laceration of the vagina, about an inch and a half in length, a short distance from its superior extremity.

“By reverting to the uterus, we found the deficient parts attached to it, viz. one fallopian tube, entire; a portion of the broad ligaments, and about an inch of the upper end of the vagina, which had been divided by an even circle, though manifestly without the aid of any cutting instrument. The external surface of the uterus was about half denuded of its peritoneal coat, leaving the muscular fibres entirely bare. Its internal surface was smooth, and the part where the placenta had been attached very apparent, presenting a slight brown colour. The whole organ was about the size of a child's head at birth. Large quantities of coagula were about the body; the bedding was thoroughly soaked with blood, and a large puddle of it, of a bright red colour, covered the floor beneath the bed.

“The examination of an intelligent female witness before the coroner's jury, developed the following facts:—Immediately after the *quasi* doctor arrived, he took hold of the cord, and making strong traction upon it, he completely inverted the uterus, the placenta still adhering; pulling still harder, he severed the cord from its attachment, and gave it to the witness. He then took hold of the placenta, removed it, and laid it aside, saying there was more to come away still. He then grasped the uterus of the unfortunate patient, and by dint of “excessive” pulling, after about three-quarters of an hour (during which period he relaxed his efforts occasionally to rest and remove his coat, the miserable patient constantly uttering the most piercing and heart-rending cries, such as “you are tearing my heart out,” &c.) he succeeded in dragging the uterus from its attachments, and separated it from the body, holding it in his hands, and exhibiting it as a proof of his prowess and skill, saying that “he never had met with such an extraordinary case before.” When asked what it was, he replied “either a polypus or a false conception.” During this brutal operation, the groans of the suffering woman were at first strong and loud; these, together with the force which the man was seen to use, excited the alarms of the attendants, who urged

him to desist, and allow other medical advice to be called; but with incredible hardihood he persevered, insisting that all was right, that she must endeavour to be patient, and that *he would be responsible for her life*. Towards the close of the performance, her cries became more and more faint, and at length entirely ceased. He thought she was endeavouring to support the pain with patience, and encouraged her in so doing by words. When he turned to look after her, and to feel her pulse, he found that she was dead.

"It is due to the profession to say, that the performer of this horrible tragedy is not, *de jure*, a member of the profession, though he asserts that he has a *recommendation* from three surgeons of the British Navy, of his medical proficiency, and that he has had a large amount (three hundred cases) of obstetric practice. He appears to be about thirty-two or thirty-three years of age, and has been in this country two years."

Three other cases are then mentioned; one occurred at the town of Pulaski, in the State of New York; one is recorded by Bartholinus; and one is to be found in the *Medico-Chirurgical Review* for April 1836.

The trial of Hunter for this offence was concluded on the 15th of June. He was found guilty of manslaughter in the fourth degree, with a recommendation to mercy, and the sentence was imprisonment for a year in the Penitentiary.

The extirpation of a portion of rib (the tenth of the left side), for neuralgia, proved successful.

These articles are followed by hospital reports, a translation of a French essay on the tubercular disease of the bones, bibliographic notices of twenty-two books, and scientific intelligence. Under the last head we find two cases of lithority, by Dr. Alban Goldsmith. In the first, the patient was thirty years of age, and the calculus was composed of uric acid; in the second the patient was sixty, and the calculus was composed of phosphate of lime. Both operations were perfectly successful. On the whole, this journal does credit to the well-directed industry of our brethren of New York.

## MEDICAL GAZETTE.

Saturday, September 28, 1839.

"*Vixit omnibus, licet etiam mihi, dignitatem Art. s. Medicæ tueri: potestas modo vendendi in publicum sit, dicendi periculum non recuso.*"

CICERO.

### A FEW WORDS TO PUPILS.

IN the introductory lecture with which it is customary to preface the sessional instruction of a medical school, the teacher may either address his audience generally, on the relations of our profession to society, and the duties which result from them; or, specially, on the best method of learning each branch of the medical art. Perhaps we shall not go wrong, if on the present occasion, with a medical new-year just before us, we take a page or two from each of these supposed lectures, and address our younger readers, both as citizens and practitioners; without, however, confining ourselves entirely to the fresh men of the season.

In these days of extreme, we had almost said of insane, competition, the number of medical schools in London has increased to a lamentable extent; for lamentable it must be to every friend of the profession, when he considers the evils which arise from this hungry rivalry to pupils as well as teachers. To the teacher a lectureship in a minor school is often no more than a decent method of advertising; the profits, if profits they can be called, being insufficient to pay for the cabs which convey him to the scene of mortification. So that those classical or mathematical tutors who placard their services at eighteen-pence an hour, work at a more gainful trade.

Then to the pupil the system is hurtful, from the languid manner in which instruction must too often be doled out,

when the teacher's labour has no reward. Actors do not play with great spirit when there is one pound five in the boxes, and eighteen shillings in the pit; and a lecturer is not supposed to be much cheered, nor his powers of expression greatly quickened, by a class of six\*.

In fact, here, as in other cases, extremes meet; and as want of competition leads to the carelessness of monopoly, so a superfluity of it produces the recklessness of despair. In London, the days of monopoly, if they ever existed, have long since passed away, and we have arrived at the era of ticketing, placarding, and underselling. It will not be long, probably, before we see ambulatory boards asking, "Why pay three guineas for a course of midwifery, when Dr. Grubb sells as good for thirty shillings?"

Now, the bearing of all this on the interests of pupils is obvious. If schools were few and far between, and conducted by those only whose rank and standing in the profession gave some guarantee of the soundness of their institution, though there still might be a difference in their merits, yet so scrupulous and jealous a selection would not be necessary; but now that too many schools are merely advertisement offices, we would put pupils on their guard; and as they eschew razors made, not to shave, but to sell, so they should keep clear of lectures compiled, not to instruct, but to puff.

Hence we advise the student, either to repair to a school where the high professional rank of the lecturers is a pledge that they know what they teach; or, if this is too much to ask, let him at least select one where the diligence and respectability of the teachers compensate for want of fame, and where their

greater leisure allows them to be tutors as well as lecturers\*.

Avoid therefore, we would say, those lecture shops where cheapness and easy certificates are the chief recommendations; where the pupils are more remarkable for drinking, smoking, and *larking*, than for reading; where there are a majority, who, in the words of a medical tutor which we lately quoted, "work more to pass than to learn; who fear an edifice hard by Bridge Street, and dread the approach of Thursday nights."

The coarseness of manner and violence of language prevalent at such places are not to be considered as trifling failings, nor as slight hindrances to the professional success of the student. He is to recollect that the office of the practitioner is not merely to solve medical problems on paper, but to diminish pain, and pluck a few units from the vast sum of human misery, by every possible method. The raw beginner thinks that his office is only to administer drugs; but unless he remains a beginner for ever, he soon learns how much may also be done by advice, concerning dress, diet, lodging, exercise, and the other details of hygiene.

But even this is not all; indeed, if the medical man has no moral influence with his patients—no power of persuasion, he is at best but half a practitioner. Baglivi observes, that even the power of drugs is increased when they are prescribed by a man of celebrity; much more, then, will all the other appliances of the healing art gain in force when in the hands of moral worth. The vulgar practitioner is naturally taken by his patient to be a mere prescribing machine,

\* If several assistant physicians were appointed at each of our hospitals, whose office should be to teach physic to the pupils, by taking them to the homes of out-patients, while the more advanced students were entrusted with cases, under the supervision of the physicians, this would be the greatest possible improvement in medical education. Such an institution is called in Germany a *polyclinic*.

\* Such classes seem to have been occasionally known even in former times. Menage was acquainted with a professor who, to make up an audience, was obliged to beg his friends to be present. On asking one of them why he had stayed away, he replied, that he was afraid of breaking in upon his solitude.

and not an adviser warranted to interfere with his modes of life. In nervous diseases, whether they require firmness or soothing on the part of the physician, this influence is immediately seen; but there is scarcely any case where it is completely null. The biographer of Dr. Denman says of her father, "such was the tenderness and sympathy of his manner, and his devoted attention to the claims of humanity, that many a sick bed was soothed and comforted by his kindness and conversation, long after it was known that no advantage could be expected from his medical assistance\*."

In truth, if the office of a medical practitioner is to relieve pain, how can he expect to succeed when he inflicts it by voice, gesture, and conversation? It would be a miracle if any one had ever got on, even in days of less competition, against such disadvantages. Most of the alleged instances of successful bearishness are deceptive; for the obnoxious manner had been concealed or mitigated until reputation was established, and was then brought out in high relief by the intoxication of prosperity.

Every profession, it must be confessed, has its own defects; not so far its own, indeed, as to be its peculiar heritage, but so far as to be commoner in that one than in others. Each mode of employing the mind gives it a twist, as each manual trade is attended by its physical defects. The lawyer is often found to think more of law than of justice; the long pursuit of his profession habituates him to calculate rather the value of his cause *in banco Regiæ*, than its real weight before the tribunal of *Astræa*. "Our client has neither law nor equity in his favour," said an advocate to the attorney, "but he may take the chance of a jury."

Now, if we may venture to touch on a matter of such extreme delicacy, and hint a fault which naturally clings to our profession, we would say that the practice of physic tends to produce a less acute sympathy with suffering than is to be found among those to whom the sight of pain is less familiar. Perhaps this maxim may be thought to go too far, and we readily grant that it must be taken with great allowances. The medical practitioner who does all that skill and kindness can suggest to relieve his patient, cannot be said to be deficient in real sympathy, though he no longer has that instinctive thrill with which the inexperienced portion of mankind regard severe suffering; indeed, had he too much of this fellow-feeling, it would cloud his intellect, and make his opinion on the case less valuable.

The practitioner mentioned by Cooke, in his work on Nervous Diseases, who became jaundiced whenever he had a dangerous case under his care, might be the most amiable of men, but could hardly be the most clear-headed of physicians.

But it is not, of course, to this scientific equanimity that we refer, for the warning of pupils; for this is to be cultivated: it is a studied and criminal indifference which is to be shunned.

The candid, however, will confess that this voluntary apathy is met with oftener than we could wish, and oftener than we might expect. When physic is adopted as a profession by one who has neither moral refinement, nor that polished deportment which often serves as a varnished substitute for it, it must be allowed that the callousness produced in the culprit is sometimes frightful. As drunkenness is said not to create new faults in its subject, but merely to bring out those which self-restraint had prudently concealed, so it may happen that an ill-chosen pursuit will educe failings

\* Memoir of Dr. Denman, in the sixth edition of the Introduction to the Practice of Midwifery.

that under happier circumstances might have slept for ever. For intoxication itself, though said to be merely the exaggerator of existing vices, and not the creator of new ones, still, like a magnifying mirror or a microscope, proclaims many that would otherwise have escaped the most acute observer. Thus the tone of familiarity with patients may degenerate into an abrupt coarseness; or the license on sexual subjects, warranted to a certain extent by professional circumstances, may be supposed, as we have seen in more than one shameless example, to authorize the publication of books which deserve to be prosecuted by the Society for the Suppression of Vice.

The judicious student will not misunderstand us. We do not desire to see in him the high-wrought sympathy of a woman, nor even that degree of it which we might wish in one unaccustomed to the objects which daily meet his view; but we request him not to exaggerate his indifference, not to give the details of the dissecting-room at the dinner table, nor to triumph too much when he has got over the innate feeling which makes the rest of mankind contemplate with horror the ravages of disease, and the contortions of pain. We can assure him that all this is as contrary to the tone of good society as it is to good feeling. If a gentleman indulges in the exercise of rowing, he does not continually poke his hands in people's faces to show how hardened they are.

## REMOVAL OF AN ENORMOUS FIBROUS TUMOR OF THE UTERUS.

BY M. SCOUTETTEN.

MADAME R., a lady of easy circumstances, at Metz, is forty years of age, strong, and of good constitution; she has had several

children, and her labours have always been unattended by any bad effect. In 1831 her catamenia were disturbed; afterwards abundant but easily repressed hæmorrhages supervened, without any evident cause; and they were accompanied with sensibility in the epigastrium, and of derangement in the digestive functions.

Notwithstanding the evident progress of the disease, and the increasing swelling of the abdomen, the patient was but little distressed, when suddenly, in April 1837, she was attacked with a considerable hæmorrhage, which she attributed to fatigue. She went to bed, and a few instants after she felt a shock, followed by pains like those of labour, which increased and succeeded each other rapidly. An accoucheur was called, who discovered by the touch a very long tumor engaged in the neck of the uterus. The patient remained two days in a state of horrible suffering; it was hoped that nature might be able alone to relieve her. The seriousness of the disease and the imminence of the danger suggested a consultation, and I was called in. I found, by an attentive examination, that the tumor was hard, resisting, and smooth on its surface, and had the principal external characters of a fibrous tumor.

The patient was placed on the edge of a bed, her legs and thighs being separated and fixed, and I introduced my fingers into the vagina in the hope that they might be sufficient to draw the tumor out, but I soon found that this was impossible. I then took strong toothed forceps; they tore the surface of the tumor, but could not move it. I tried to pass a thread round the tumor with a *serre-nœud*, but the ligature slipped, and fell off directly. I then introduced a long and narrow forceps cautiously into the cavity of the uterus, and with them the tumor was seized and slowly drawn out; I found that it was fixed by a large surface to the interior of the uterus, and that that organ was inverted. Was I now to divide the attachment with the bistoury? I should so expose myself to a hæmorrhage that might be fatal. Was it not more prudent to confine myself to the application of a ligature without endeavouring for the present to return the uterus? I knew that I might thus excite inflammation of that organ and peritonitis; but I preferred to expose myself to combat an inflammation rather than a hæmorrhage that might be at once destructive.

I therefore put a strong but fine ligature on the tumor at its attachment; it was drawn tight and the tumor almost immediately became brown, which I attributed to the arrest of the blood in the numerous vessels that traversed it. I sur-

rounded it with a compress covered with cerate, and placed the whole between the thighs of the patient.

During the first day the abdomen was tense; but only slightly painful, the pulse scarcely febrile. I ordered only a friction of oil on the abdomen and the application of a cataplasm. On the next day, the patient suffered a little more, but there was no serious symptom. On the third the weight of the tumor had lengthened the cellular bands which united it to the uterus nearly half an inch, and it was now easy to see that they might without inconvenience be divided with the knife: I did so at once: the tumor was removed, the uterus gently pushed back, and all the bad symptoms disappeared.

Twelve days after, the patient was so far recovered that she could go out and walk: and since that time her health has never been a moment deranged. The tumor weighed 35 ounces; it was ovoid; its great circumference measured  $16\frac{1}{2}$  inches, its middle circumference 12 inches and five lines; its tissue was composed of concentric fibres.—*Gazette Médicale*, Août 24, 1839.

### HABITUAL DISCHARGES.

I HAVE KNOWN many persons, with whom the least diminution of an habitual discharge was presently followed by feelings of impaired health, and occasionally by actual mischief. The following case may not be uninteresting, as exhibiting this alternation in a remarkable degree. It is given in a condensed form, from notes made during the attendance.

Lady R...., at the age of 79, had bronchitis in 1829, and was so ill that her recovery was despaired of. She had cold extremities, intermitting pulse, great dyspnoea, and difficulty of expectoration. Wine given freely, and the appearance of an eruption on the legs, saved her for the time. The expectoration which then occurred became habitual, and the eruption, which was generally of a pustular character, continued till the period of her death in 1831.

On one or two occasions the discharge from her legs diminished, and then the cough became hard, and the breathing frequent and oppressed; but when the discharge from the limbs reappeared, the bronchial affection subsided to its ordinary state. She was seized at length in 1838 by the catarrhal influenza prevalent at the time. It began with rigors and such a degree of collapse as nearly annihilated her. The legs literally "dried up" at once, the discharge ceased, and they became cold and livid. The usual symptoms of the influenza set in with great violence. Under the most persevering attention of

her friends, the heat of the limbs was restored, and the stage of mucous secretion in the bronchial membrane was attained; but she sank, literally from inability to expectorate.

I have at this moment under observation an elderly gentleman, who has succeeded, for the second time in twelve months, in nearly healing two ulcers, one on each inner ankle, connected with a varicose enlargement of the veins, of long standing, and he is already beginning to complain of suffocation on going up stairs, annoying cough, and occasional vertigo, during which he is frequently blind for two or three seconds. — *Mr. Ferrall, in Dublin Journal.*

### APOTHECARIES' HALL.

#### LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, Sept. 26, 1839.

Mr. Henry Brown, Lewisham.—Thomas Sankey Cooper, Canterbury.—Thomas Blackledge Garstang, Settle.—Thomas Holyoake, Salop.—Charles Redfern, Barton.—John Cox, Oxford.—John Rose, Oxford.—Joseph Schofield, Saddleworth.—William Egginton Thompson, Worcester.—John Harmer Smith, Sheffield.—Christopher Leech, Settle.—Alfred Homfray, Clifton.

## THE CROONIAN LECTURES

FOR 1839.

BY JOHN CLENDINNING, A.M. & M.D.

Of Oxford, &c.

*As delivered at the Royal College of Physicians,  
May 15, 17, 22.*

### ON THE DIAGNOSIS OF DISEASE OF THE HEART.

*Extent and Momentum of Impulse—Varieties of Cardiac Sound with Healthy Valves—Diffusion of the Sounds, normal and abnormal—Hydrothorax, Empyema, and other cases.*

*Mechanical signs—Extent of Impulse.*—The next points for observation are 1. the extent of the heart's action as measured by sensible impulse. 2. The development of the heart, as evinced by the momentum of that impulse. 3. The area over which the systolic and diastolic sounds can be heard.

The first observer, I conceive, that gave the stamp of authority to the method of diagnosticating enlargement of the heart by the superficial extent of the heart's sensible throb, was Senac. Since his time it has been verified by every subsequent observer, and no doubt at all can be entertained of its value in favourable cases. The hand being placed transversely over the cardiac region, with the points of the fingers beyond the nipple, and the palm pressing on the cartilages, or *vice versa*, the throb of the heart is readily felt and easily measured lineally, provided only the action of the organ be sufficiently vigorous, and provided also there be no considerable mass of intervening lung suspended like a cushion between the impinging body and the pectoral parietes.

But the former condition is often wanting. The heart's action is not unfrequently, whether transitorily or permanently, languid, and then the sensation of locomotion

attributable to the heart is difficultly distinguishable from other sensations communicated by the parietes of a cavity subjected at all times to several distinct sources of vibratory motion: viz. 1, to the cardiac impulse; 2. the action of the respiratory muscles, and 3, the various reverberations of the breath and voice. Under such circumstances recourse must be had to other signs. This, however, may be noted, that in some cases the difficulty may be at once surmounted by making the patient suspend his breath for a short time, during which, it will often, if the heart's action be not very feeble, be possible to measure the area over which that action is sensible. There is also another way of making this manœuvre available, viz.: by exciting the heart by some sufficient voluntary effort, or by some stimulant administered for the purpose, or else by making the examination immediately after food or cordial medicine.

But in a large proportion of cases the action of the heart will usually be found more or less energetic, and in those cases we have double means of diagnosis,—1st, the extent over which the systole can be felt, and 2d, the momentum of that systole. With regard to the extent, it varies much, according to the size of the heart and the energy of its systole; according also to the state of the pericardium, whether adherent, or dropsical, or otherwise; according also to the condition of the lungs, whether spongy or solid, emphysematous or œdematous, expansible or compressed. But the points most important to explore seem to be, 1, over the base on the cartilages; 2, over the apex under the mamma; 3, in the epigastrium; and 4, over the middle or upper pulmonary lobe, somewhere in a vertical line with the middle of the clavicle.

By observing the distances between the extreme points at which the throb or systolic impulse is perceptible, the develop-

ment is easily measured with sufficient practical accuracy. Owing, however, to one or other of the sources of difficulty above referred to, and especially to emphysema, or to hydro-pericardium, or to cedematous condensation, or to consolidation, of the lung, I have myself often been unable to obtain satisfactory indications of enlargement by this method. For even though the systole have been pretty vigorous, still its impulse, when impeded by pericardial adhesion, or by hydro-pericardium, has been slight and easily missed or doubted of; and when the heart has been separated from the pectoral parietes by a diseased lung, it has not seldom been found difficult by this means to estimate its condition. Again, if the lung have been too porous, as in emphysema, the impulse has been absorbed altogether, or but very partially transmitted; and if the lung have been too solid the same impulse has been transmitted readily, and diffused widely, and, I think, occasionally much beyond what it could possibly be, had the pulmonary substance been normal. In such circumstances, and the subject being in a state of perfect repose, I have been sensible of impulse on the posterior surface of the chest, a point to which it could not easily reach under less favourable pulmonary conditions. The diffusion of the heart's impulse, therefore, as a diagnostic mark of morbus cordis, is liable, like other signs, to important sources of fallacy, which, though usually not ultimately sufficient to baffle the practised hand, present not unfrequently formidable obstacles, especially to the junior practitioner. The following are the most important embarrassing combinations I have myself met with—1. the difficulties occasionally and not very rarely arising from the coincidence of pulmonary condensation, including diminished resonance, with increased conducting power in the lung, and hepatic enlargement with hypertrophy of the heart, have often proved to myself very embarrassing.

2. The co-existence, not by any means very rare, of extreme emphysema of the edges of the lung in the cardiac region, with disease of the heart, has likewise occasionally conspired with hepatic enlargement, or distention and high elevation under the ribs, of the stomach, to render for a time, accurate and certain diagnosis by the ear wholly impracticable. Were the stomach the only source of difficulty, carminatives, &c., no doubt might be used to expel flatus, or the resonant cavity might be diminished to any extent by drinking, or a meal; but the pulmonary and hepatic morbid conditions must prove permanent obstacles.

*Momentum of impulse.*—With respect to

the momentum of the systolic impulse, there is little observation required. When the impulse is well marked, there can be little room for doubt as to whether the impinging body be massive or small, light or heavy. It is a matter of direct inference from simple sensation, and the conclusion follows directly after experiment, whether affirmative or negative, of disease. A vigorously acting heart of moderate size may and will give a considerable impulse, considerable, I mean, for its weight and quantity of matter, but nothing that can be mistaken by competent observers for the stroke of a heart in a condition of sthenic hypertrophy. This sign, therefore, being simple and mechanical, is not subject to material error. It is, however, frequently insufficient in cardiac diagnosis; in those cases, namely, where the systolic action is feeble or at least insufficient to overcome such impediments, as emphysema, or other pulmonic complications above alluded to. On this head there is but this further observation to offer, viz. that the force of the heart's impulse is a diagnostic sign only when it yields *positive* results. When the result is *negative*, no inference can be drawn, opposed to the supposition of cardiac hypertrophy and enlargement, for reasons which will be obvious when we call to mind the frequent occurrence of habitual sluggishness of action in the absence of unusual excitement, and even of absolute debility, in the parietes of the thickened and enlarged heart.

We come now to the consideration of the sounds of the systole and diastole, so far as they throw any light on hypertrophy of the heart.

*Preliminary explanation.*—Before entering on the consideration of the diagnostic value of the principal modifications undergone in morbus cordis by the systolic and diastolic sounds, it is necessary to remind my hearers very briefly of the mechanism of those sounds. Since the publication of those researches of Laennec which have led the way to recent minute investigations of that mechanism, a complete revolution has taken place in the views of pathologists respecting the cardiac sounds, nor has a general agreement been yet arrived at on many points of the subject. But already certain leading facts are on all hands admitted, and certain others are, though not yet generally admitted, still I conceive so certain, that it is necessary for my purpose in more respects than one to devote a few words to them.

It is generally admitted, 1st, that there are two normal sounds attending the heart's action; the one coinciding with the systole, the other with the diastole. 2d, that those sounds when normal are easily distinguished by the gravity and

protraction of the one, and its synchronism with the arterial pulse and cardiac impulse; and the shortness and sharpness, or abruptness and clearness, of the other, and by its synchronism with the subsidence of the heart, and the interval between its strokes upon the parietes of the chest. 3d, that each sound is produced by changes of physical condition in the cardiac fluids and solids, either conjointly or severally considered, changes coincident with the systolic and diastolic efforts respectively, and necessarily attending upon and involved in the heart's action. 4th, that the ventricles are the principal active or vital agents in the production of both sounds. 5th, it follows from the experiments of Dr. Hope, and the more recent and decisive experiments of my friend Dr. C. J. B. Williams, and of the Committees of the British Association in Dublin and London, that the diastolic or second sound is, in all probability, simple, and dependent on the sudden tension and closure of the arterial valves, which repel the blood recoiling back from the aorta during the dilatation and repose of the ventricles: and that the first or systolic sound is probably complex, depending principally on the muscular sound attending the contraction of the ventricles, and partly also on the valvular action in the auriculo-ventricular or interior orifices\*.

6th. From the same experiments it follows that the auricular action is unattended by any sound depending on such action.

Assuming, then, those positions as data, I shall consider the subject of the sounds of the heart under three heads, viz.:—

1. The characters of the sounds in themselves. 2. The diffusion of them. 3. Their purity; i. e. their freedom from, or intermixture with other cardiac sounds, and their distinctness, or else their absorbed or masked state, when modified, owing to the coexistence of other and louder abnormal heart sounds.

The third series of observations I shall here omit, as they will be included in what I shall have to say under the head *valvular disease*.

To proceed, then, with the first and second heads.

*Varieties of cardiac sound with sound valves.*  
—The principal varieties that I have ob-

served in the characters of the first sound are, 1st, abnormal obtuseness and duration 2d, abnormal loudness and clearness.

The former character of *systolic* sound is usually combined with apparent slowness of contraction and a tardily completed systole—thence the sound is more than normally prolonged; and the gravity or obtuseness of its tone is generally referred, and I believe correctly, to the massiveness of the walls in such cases usually observed post-mortem. With respect to this variety, I think there can be no reasonable doubt that a systolic sound at once abnormally obtuse or grave, and prolonged, indicates with something approaching to absolute certainty, cardiac hypertrophy, and most probably also cardiac enlargement.

The second variety of systolic sound is the abnormally short, shrill, and clear sound, approaching the normal character of the second or diastolic sound. This is a variety of the first sound of no rare occurrence. I imagine there are few advanced cases of *morbus cordis*, few at least that have reached the asthenic stage, that supervenes sooner or later in almost all cardiacs not incidentally cut off early in life, in which systolic sounds of this kind may not occasionally if not constantly be observed. This character seems to me to attend very commonly every sudden excitement, in subjects with hearts grown inapt for vigorous concentric action, owing to abnormal fleshiness and volume: that I have observed it numberless times, in hearts proved post-mortem to be much and even enormously hypertrophied, I unhesitatingly affirm. It does not very well accord, indeed, I believe, with the statements of authors, that it should be so; for the variety of systolic sound I am at present considering is the same that I find in books of authority, attributed to a state of heart development nearly opposite to that in which I have so frequently observed it; to a state, namely, of enlargement with attenuation, or relative atrophy, of which condition the sort of sound in question has been held to be a diagnostic mark.

With much and sincere respect for preceding writers, I must say, however, that I doubt whether the semeiology of passive aneurism is much better than an ingenious speculation, founded on a few misinterpreted facts. Omitting special notice of the speculative part of the subject, the facts misunderstood seem to be these:—The hypertrophous heart under various circumstances, contracts quickly, but partially, and abruptly relaxes into diastole again; and in this way gives an abnormally short, sharply defined, clear first sound. This seems the probable fact when the first sound is short, the second relatively long, and the interval between the sounds likewise pretty long.

\* The original experiments and observations by which this element of the systolic sound has been substantiated to the satisfaction of the London Committee of the British Association, were made in the earlier part of 1838, and anteriorly, and remain as yet unpublished: they confirm the views of Professor Carswell, Dr. Billing, M. Rouanet, Professor Bouillaud, &c. as to the acoustic results of valvular action, and coincide very nearly with the careful and able statements of Dr. Hope, which were being published, I perceive, just about the period of the preparation for delivery of these Lectures; viz. May, 1839.

But it also happens that a prolonged and complete systole may give but a short sound. This may occur in cases of considerable cardiac asthenia, in which the commencement of the systole may be audible in the form of a short clear sound, partly valvular, partly muscular, although the latter part of the systole, succeeding the moment of valvular tension, may, owing to sluggishness or feebleness of contraction, be inaudible through lung, muscle, bone, skin, hydro-pericardium, and other impediments, whether natural or adventitious, interposed between the ear and the heart under examination. In either of these ways it is obvious that a heart more muscular than normal, may, notwithstanding, manifest its vitality by sounds more obscure and feeble than normal. The hypertrophous heart may therefore easily pass for attenuated with the speculative cardiologist, who, while pursuing subtle reasons, which are commonly but anodynes of aching curiosity, or as it were, a sort of intellectual placebo, is not unlikely often to overlook gross and palpable phenomena.

Such seems to me, according to my present information, the proper interpretation of those matters of fact on which has been constructed that portion of the fabric of cardiac semeiology that relates to passive aneurism. It follows, therefore, according to my views, that a short, clear, systolic sound, indicates not so much any particular anatomical state of the heart, such as atrophy or expansion, or the reverse, but rather a defective dynamic condition; that it indicates, in a word, not *attenuation* of the parietes, but merely *debility*.

*Diastolic Sound.*—The abnormal varieties of the diastolic sound which are developed independently of valvular lesion, are less important, very much, than those of the first sound. They occur frequently enough, but have not the ascertained constancy of connexion with any particular morbid organic conditions, that would be necessary to give them diagnostic value. The variety most commonly met with is a prolonged and voluminous sound, approaching in character to the first sound; but the cause or causes of this modification I have not ascertained. I am not aware that it is wholly incompatible with health.

*Abnormal rhythm.*—There is another class of modifications to which the systolic sound more particularly is liable, not above referred to, viz. what I may call intermittence. By this I mean an apparent abnormal frequency of recurrence, owing to the systolic act being subdivided into two or more distinct efforts, between which are interposed moments of relaxation or repose. This double or triple throb has repeatedly fallen under my observation. I have had also opportunities

of examining, post-mortem, cases in which this had been observed during life. The best marked case of the class I recollect, was that of a shoe-maker, who had become a subject of morbus cordis in consequence of a blow of a hammer on the cardiac region. He was twice under my care in the St Marylebone Infirmary, and recovered pretty satisfactorily of his first complaints, and was discharged free from pectoral uneasiness, with a heart considerably enlarged, but yet performing its duty regularly and well. Some months after, however, the next winter I think, he returned with, at first, dropsical symptoms, including much pectoral distress. His second course of treatment was protracted, and was brought to a close by the super-vention of pericarditic symptoms, during which was noticed the intermitting systole, giving sometimes double, often triple sounds, and occasioned, I conceive, by rapid remissions and resumptions of the tense condition that characterizes the cardiac contractions. In the post-mortem investigation of this case we found the heart and pericardium adherent to such an extent as might readily be conceived to be very embarrassing to the cardiac functions.

But though in this case the anatomical conditions might suggest an obvious explanation, founded on a basis in some measure mechanical, yet I have seen similar systolic irregularities, too often, where no adhesions existed, nor other equivalent structural impediment, to be disposed to refer the reduplication of sounds in that case solely to the morbid changes found post-mortem, and, indeed, expected during life. On the whole, the impression on my mind is, that the essential element in such irregular actions is cardiac debility, and inadequacy of the contractile energies of the organ to the propulsive efforts required of it—a state of debility I have never seen wholly unconnected in morbus cordis with muscular hypertrophy. And this conclusion is confirmed by the fact, that the acoustic phenomena under consideration have been repeatedly observed, in cases of morbus cordis with extreme valvular contraction and induration, and under circumstances, therefore, in which complete evacuation, by a single systolic effort of a ventricle capable of holding even a few drachms, was mechanically impracticable; circumstances, also, in which the existence of relative debility or muscular inadequacy of power was placed beyond a doubt.

With respect to the diastolic sounds, I do not recollect any well-marked case in which reduplication of them, in any way like the preceding, referable to the first sound, has ever fallen under my no-

tice; and it seems probable that such reduplication can only occur in rare and complicated combinations of things. The second sound, it must be recollected, is immediately produced by impulses much more constant and regular than muscular contraction—viz. 1. the reaction on its contents, after the systole, of the distended and elastic aorta, which is the cause implied or expressed by the Committees of the British Association, and by several distinguished private experimentalists, British and foreign; and 2. probably also partly, if not principally, by an expansive effort included in the general diastole, and extending to the arterial openings, so as to distend them rapidly, and give to the valvular laminæ that *sudden tension* that immediately produces the diastolic sound. Now, of those agencies the former is wholly mechanical, being but the reaction of an elastic tube forcibly distended; and it is, therefore, liable to no such variations as are, strictly speaking, vital agencies, such as muscular contraction. And the latter, or cardiac expansive effort, is but partly, I should say, a vital agency—viz. so far as the diastole can be considered as other and more than mere relaxation—as other than the effect of that tendency to repose which all bodies are influenced by. This latter force—I mean the forces that excite the second sound, are therefore, it is probable, comparatively little subject to spontaneous alterations in their mode or power of action. Whether, however, the reasons just sketched be correctly stated or not, there can, I think, be no doubt of the comparative insignificance at present of any modifications observed in the character of the diastolic sounds. It is therefore useless to dwell on them.

The next topic for our consideration is the diffusion of the cardiac sounds over the pectoral parietes.

*Diffusion of the cardiac sounds.*—It seems, *à priori*, probable that an enlarged heart, coming into contact mediate or immediate with an increased number of points on the walls of the chest, would diffuse more widely its sounds, and be on the surface perceptible by the ear, both in systole and diastole, over a greater area than normal: and practice to some extent confirms the presumption. Were, therefore, the cardiac action at all times sufficiently vigorous, and were the heart always in the same local relation to the pectoral walls, as to distance, position, &c.; and, finally, were there no intervening bodies of variable bulk and density;—on the supposition that in none of the quarters just alluded to did sources of fallacy exist, it would seem that the diagnosis of morbus cordis, so far as deducible from the width and manner

of diffusion of the heart's sounds, were abundantly easy and simple. But the facility is more apparent than real; and there is no one cardiac symptom, perhaps, more fallacious and difficult rightly to estimate than this. For the heart, though large, may be prevented from diffusing widely its sounds by obstacles within the pericardium or without; and the heart, though normal, may, through exterior favouring circumstances, be enabled to make itself audible at nearly the remotest corners of the thorax. The impediments that I have noticed within the pericardium, are—

1st of all, of course, too weak action in systole and diastole.

2. Adhesion to the pericardium to a great extent.

3. Copious hydro-pericardium.

And the impediments without the pericardium are more numerous and various still. They may be ranged under the following four heads—viz.

1. Increased density in the lungs.

2. Diminished density in the lungs.

3. Liquid effusion in the thorax.

4. The pulmonary abnormal sounds.

Before entering, however, upon the practical consideration of the obstacles to an abnormally extensive audibility of the heart's sounds, I must premise a few sentences relative to the normal extent of their diffusion over the pectoral walls.

*Normal extent of diffusion of the cardiac sounds.*—At different periods of life, there are great differences in the dimensions of the pectoral cavity, and in the development and density of the lungs. In the child, the chest is, I conceive, relatively to the cranium and abdomen, more shallow and less capacious than in the grown man; and the pulmonary substance is at the same time, as by the test of specific weight I have satisfied myself, much more dense in the former than in the latter. Then, with regard to sexual modification, it may be said that the male exceeds the female, in relative pectoral dimensions, considerably (on account, no doubt, of the great development of the pelvis in the female after puberty), and very much more relatively to the abdominal cavity, than the adult exceeds the child. Thus, then, the general volume of the lungs, and the thickness of pulmonary texture, that must be traversed by the cardiac sounds in various directions, in order to reach the surface, is variable to a considerable extent, according to age and sex.

There is also to be noted a variability (not very great, indeed, between puberty and incipient old age) in the texture of the lungs, with regard to density; which, so far as it affects the conductive qualities of the lung, must modify the stethoscopic phenomena.

Then there are personal differences of conformation requiring allowance—viz. great transverse amplitude or narrowness, and great vertical or antero-posterior depth or shallowness of the chest.

Another class of differences consists of varieties in the *timbre* and *pitch* of the cardiac sounds: It is plain that acuter sounds are more readily, and obtuser and graver sounds less readily transmitted; and that the former are less easily, and the latter more easily muffled and suppressed. The general effect of this normal variability, according to age, sex, conformation, &c. in the conditions favouring diffusion of cardiac sound over the surface of the thorax, is this: that there is almost no point on the anterior aspect of the chest, and no very considerable area on the lateral surfaces, where the cardiac sounds may not, in persons above puberty, especially females, occasionally be heard, without implying disease; while in a very large section, and that in several respects the most important section of civil society, the distinct perception, in a state of repose in the horizontal posture, of the heart's sounds, over more than a few dozens of square inches of the chest, and those in the proper cardiac region, is, according to my observation, a rare occurrence; and is, unless in slender frames, or after exercise or equivalent excitement, in most cases, if not always, symptomatic of pulmonary disease, with or without cardiac complication. The important class I allude to is that of adult males, from 25 or 30 to 55 or 60. But in children, the normal extent of diffusion of cardiac sound appears to me to exceed by much that of any other class; and this is owing to various favouring conditions, viz. 1. Greater density, and consequently superior conductive power for sound, in the pulmonary structures. 2. Comparatively closer proximity of the surface of the chest to the sonorous body. 3. The more acute pitch, and therefore more easy transmissibility of the sounds. Accordingly, in children I have often heard the cardiac sounds on the left posterior aspect of the chest without disease, and over most parts of the left anterior and lateral aspect; and on the right anterior aspect they will commonly be found audible to a practised ear, at least in the intervals of respiration; while, after exercise, they may in such subjects be heard all over the thorax.

Besides the physical conditions just pointed out, as favouring or impeding the transmission to the surface of the cardiac sounds, over a large area, there are certainly other influential conditions, of whose existence I have no doubt, but which I have been unable to identify. Almost

every other student and mental labourer, for example, has personally experienced this, if, of course, his attention have been given to the matter—namely, that at moments of cerebral excitement, accompanied by vigorous action of the heart, the dyastolic sound at least (and often both sounds) has been perceptible to him in his own person, without any search for it, and especially in the horizontal posture. Now the reason of this I am unable confidently to state. It seems probable that the sound, or sounds, have been conveyed along the stream gushing from the ventricle into the aorta and internal carotid; but why it is so much more easily perceived in the horizontal than in the vertical position, I see no better reason than the conjecture that in the former the arterial throb and current upwards are probably more forcible and abundant, and better fitted to sharpen the sensibility of the auditory nerve on the one hand, and more capable of transporting an ample volume of sound on the other.

Of the obstacles to an extensive audibility of the heart's sounds in *morbus cordis*, that have their seat within the pericardium, the operation is obvious. When, as in the first case, the heart's throb is feeble, its sounds are necessarily more or less obscure; and when, as in the second case, the ventricular concentric action is hampered by the adhesion to the organ of a closely investing, thick, and uncontracting wrapper of organized or organizing lymph and thickened pericardium, the systole which directly excites the first sound, and indirectly the second, is of necessity less effective, although perhaps accomplished with greater effort than in the normal state. In the third case, also, or that of copious serous accumulations in the pericardium, it is plain, that although water is in itself no bad conductor of sonorous vibration, yet that the intervention of any considerable quantity of serum between the heart and the ribs, must, in many conditions (such, for example, as that of a patient in the horizontal posture), more or less muffle the cardiac sounds; while the immersion of the mass of the heart in a medium so much more dense and less yielding than its usual mediately or immediately adjoining bodies—viz. the lungs and stomach—cannot be regarded otherwise than as unfavourable to energetic action in that organ.

With regard to those impediments to the abnormal diffusion of the heart's sounds in *morbus cordis*, which are seated outside the pericardium, this general observation may be made of all,—that they are seated in the lungs and its serous tunica; some depending on abnormal conditions of the air-tubes, others on change of

consistence or density in the lobules, others on morbid states of the pleura.

Those that depend on bronchial disease are principally chronic catarrh and emphysema pulmonum, or dilatation of the air-vesicles, with thickening, and often enlargement also, of the adjoining bronchial twigs and branches. When the action of the heart is feeble, and where the catarrhal whizzing or other sounds are loud, it is not unfrequently impracticable to hear the cardiac sounds even in the præcordia, and especially if the subject be in the supine posture. Under such circumstances, until the air-passages be relieved, auscultation can contribute little towards cardiac diagnosis.

Other embarrassing pathological conditions are—2. Change of density in the lung, either by increase or diminution of specific weight. 3. Serous or puriform effusion in the pleura.

1. It is well known that most, if not all, the important diseases of the lungs, at one stage or other, and always in the advanced stages, involve structural changes, with, in most instances, diminished porosity and increased density of more or less of the pulmonary substance. This condensation is produced in various ways, according to the nature of the morbid actions and of the tissue or tissues principally affected.

The principal modes that have fallen under my observation in cases of morbus cordis, have been the following—viz. 1. Effusions of blood into the air vesicles and lobular twigs of the bronchus, producing the pneumonic consolidations called, in different stages, hepatization, splenization, carnification, red and grey softening, &c. by different pathologists. In this condition I have found the lung equal the liver, in density and conductive power, in several instances.

2. Phthysical or caseiform matter, in and around the air-passages, and probably also in the intervesicular cellular tissue, with an hypertrophy and tumefaction, partly, at least, scrofulous probably, of the parietes of the air-tubes. This condition, I have satisfied myself, includes, in many cases, a density and specific weight not differing materially from those of the liver, which is the densest and weightiest usually of all the viscera. 3. Hypertrophy of the air-tubes and surrounding cellular tissue, with congestion of the mucous membrane, and an oedematous state of the air vesicles and bronchial ramuscles. This is a condition of the lungs I have very generally met with in that chronic bronchitis that usually attends old heart diseases, especially in the labouring classes. It is a state in which, though the lung is porous to all appearance, and tole-

rably soft and spongy in the hand, yet there is a real diminution of porosity, and an increased average density, partly owing to increased deposition of solid matter in the tissues, and partly to the substitution, to a considerable extent, of watery for gaseous fluids in the air-passages. And that this oedematous condition is not a cadaveric appearance depending on exudation of serum, &c. during the agony or shortly after death, follows from this—that during life, the chest, in such cases, has always given acoustic evidence of the existence of such fluid excretions in the bronchial ramifications; and from this also, that in an important minority of instances, more or less abnormal dullness has been detected during life, especially in the lower lobes, but also in some cases in the middle, and even in the upper lobes, in a few examples. And this dullness on percussion, has been sufficiently decided and constant to lead me, in some cases erroneously, to suspect phthysical or pneumonic induration.

2. *Emphysema pulmonum*.—But the lung may be altered by diminution also, as well as by increase of density. This occurs in what Laennec described as *emphysema pulmonum*, and is a common complication of morbus cordis. The favourite seat of emphysema is the extreme margin of the lung from where it leans against the body of the vertebræ below and behind, along the circumference of the diaphragm, to where it approaches the cardiac region, and sweeping inwards towards the mesial plane, overlaps the pericardium, and interposes its compressed border between the heart and the ribs, receiving and no doubt absorbing much of the momentum of the systole. Other parts of the lungs are also subject to this morbid state, and I have usually found that of the more central parts affected with it, the upper lobes have been, owing probably to less extensive congestion, apparently at least more inflated and lighter than the lower.

Now it is obvious that an alteration of texture and density, such as characterize the emphysematous lung, must greatly restrict the diffusion of the heart's sounds. Of all conductors of impulse, gases are known to be the worst, whether that impulse be fitted to cause sensible motion or sonorous vibrations only; and an emphysematous lung is, in effect, a mesh of thin fleshy lamellæ, which are interposed between globular and columnar cavities filled with air.

3. *Hydrothorax, empyema, and other cases*.—Of compression of the lung by serous or puriform fluids in the pleura: in such a state of things the heart's acoustic phenomena are liable to several important modifications, including in most cases in-

creased audibility in point of area. In such circumstances it may occur, if the position of the heart be altered by pressure, from the left towards the right side, that the cardiac sounds shall be more or less distinctly audible all round the central parts of the chest, on both sides of it, and on every aspect; and if the effusion be in the right chest, then also the area of diffusion will be extensive on both sides, and perhaps more extensive on the more remote side than on the nearer. The presence of fluids in the cavity of the pleura, therefore, such as just referred to, tends obviously very much to complicate and embarrass the cardiac diagnosis; for whether the heart's nutrition and volume be increased or not, great extension of audibility may be expected. So that if the effusion occur on the left side, nearly abolishing pulmonary resonance on that side, as often happens, and if the heart's vital conditions be asthenic, and its contractions and expansions be either languid and slow, or quick and abrupt, so as to simulate the passive aneurism of Corvisart—a condition likewise not very rarely met with—in that combination or any other equivalent combination of things I know of no physical signs adequate to the diagnosis of simple morbus cordis, exclusive of inflammatory and vulvular disease.

## CLINICAL LECTURE,

*Delivered at University College Hospital,*

BY SAMUEL COOPER,

Senior Surgeon to University Coll. Hospital, &c.

*Rupture of the ileum, by external violence, in a man who had a hernia, and gave a false account of himself.*

GENTLEMEN,—You may remember that, in the last sessional examination, I proposed as one of the questions—"If a patient were to receive a violent blow, or kick, on the abdomen, and to be soon afterwards brought to you with a hernia, which, for reasons unknown to you, he repeatedly but falsely declared had been occasioned by such external violence, and had not existed previously to it; what would be the considerations, justifying the inference, that the sickness, tension of the abdomen, pain about the umbilicus, and the difficulty, perhaps at first, of procuring free evacuations from the bowels, did not depend upon the hernia, but upon some other lesion within the abdomen?"

This question was suggested by the fol-

lowing very remarkable case, the particulars of which were taken by my friend, Mr. Morton, of University College:—

Joseph Thomas, æt. 40, labourer, was admitted under Mr. Cooper, at 10 o'clock on the morning of the 12th April, 1839. This man states, that as he was descending the steps leading to the area of the house in which he resided, he slipped and fell down to the bottom, in such a manner that he struck the lower part of his belly very violently against the edge of the lowermost step. He felt very sick, and vomited immediately afterwards, rejecting his breakfast, which he had taken a short time previously.

On his admission he was in a state of great depression, suffering from excessive pain in his belly, which was much swollen, and extremely tender under pressure. There is a continual vomiting, by large gulps, of a dark coloured fluid; the surface of the body is cold; the countenance expressive of great anxiety, and bedewed with a clammy perspiration. The pulse is 130, and scarcely perceptible.

There is a hernial tumor upon the left side, of the oblique inguinal form, the contents of which appear to be chiefly intestinal, and, though perfectly reducible by the pressure of the hands, descend when he vomits or coughs, and even without these actions. There is also an obscure tumefaction in the right iliac region, in the situation of the upper part of the inguinal canal, presenting all the characteristics of an incomplete bubonocoele.

The man, when questioned as to the length of time that the hernia on the left side has existed, declares that it did not exist previously to the fall, and that he believes that it has been produced in consequence of the blow he then received.

With a view of determining whether the bladder had suffered any lesion, a catheter was introduced, and about a pint of clear urine withdrawn. The bladder was ascertained to be uninjured.

12 o'clock.—The pain, tenderness, and tension of the belly, have increased. The respiration is chiefly thoracic. Pulse is now 120, and stronger than at the time of the patient's admission.

A dozen leeches to the side of the belly where the blow was received. A spica bandage and compress applied to keep up the hernia.

4 o'clock.—The previous symptoms still continue unabated, and the belly is now rather tympanitic. He complains of intense thirst, and is exceedingly restless, tossing himself to and fro in bed. The leeches have bled freely.

Fotus calidus abdomini. Cataplasma. emolliens postea.

In the course of the evening he was bled to  $\xi xvj.$ , and took a powder containing gr.  $vj.$  of calomel, and gr.  $j.$  of morphine, which was to be followed with calomel, gr.  $ijj.$  every three hours.

April 13th, 10 A.M.—Has passed an easy night, having slept the greater part of it; vomits now only occasionally; pulse has fallen to 100 beats in the minute. The pain and tension of the belly are much abated, and he expresses himself as feeling much relieved. The blood drawn is not buffed nor cupped.

10 P.M.—Is not so well as in the early part of the day. There is now more anxiety of the countenance, with the same restlessness as before. The pulse is again become very frequent and feeble, with an increase of the pain and tenderness under pressure of the belly. The vomiting of the dark-coloured fluid is now incessant. In the situation of the hernial tumor on the left side there is an evident crepitation perceptible to the finger when it is handled, as if air and liquid were effused into the cavity of the sac. The intestines do not now descend into the hernia as before, although the truss has been removed, on account of the patient absolutely refusing to wear it, in consequence of the pain which its pressure produces.

V.S. ad  $\xi xviii.$  Cont. pil. Calom.

He now gives a different account of the hernia, which he says he has had for several years, and which was first caused by the frequent coughing consequent upon an attack of asthma to which he was then subject.

14th.—The state of this man is evidently becoming much worse, although he expresses himself as feeling much relieved. The pulse is very frequent, and almost imperceptible. The extremities are becoming cold. The belly is less tender, but it is more swollen than before. As the calomel is beginning to act upon the bowels he is ordered to intermit it, and to take small quantities of brandy and water. Warmth to be applied to the extremities.

15th April, 4th day.—Has had no sleep during the past night. Is incoherent in his answers to questions that are put to him. Attempts to get up out of bed. Subultus tendinum. Pulse very frequent and feeble. Surface of the body becoming cold. He died at half past 2 o'clock, P.M., a little more than four days from the receipt of the injury.

At the inquest which was held after his death, it was proved that the injury was not caused as had been stated by the patient himself, but that it happened on the evening previous to his admission into the hospital, being produced by a kick upon

the belly which he received in a drunken brawl.

*Settio Cadaveris, twenty hours after death.*—

There is a trifling wound over the left eye-brow, with extensive ecchymosis of the adjacent subcutaneous cellular tissue. A slight bruise is perceptible externally upon the parietes of the abdomen, a little below and to the left side of the umbilicus. On laying open the cavity of the belly, the entire surface of the peritoneum, both lining the walls and investing the intestines, presented the appearance of having been intensely inflamed. There was a copious effusion of recent coagulable lymph, which glued the folds of the intestines and the omentum to one another, and these again to the internal surface of the parietes of the abdomen. About a pint of dirty-coloured serum was found among the folds of the small intestines and in the cavity of the pelvis. Some small crumbs of half-digested bread were floating in this fluid. The coats of the ileum were found to have been ruptured about three feet from the cæcum. The size of this laceration was about that of a four-penny piece; the edges of it were everted, and it was nearly closed by the protrusion of the mucous coat of the bowel. The lacerated intestine lay exactly opposite to the situation of the external bruise. The hernial sac on the left side, which was evidently of long standing, contained some of the same dirty-coloured serum that was found within the general cavity of the abdomen. On the right side, there was an incomplete bubonocoele.

No blood was passed by motions from the bowels—a circumstance which was also observed in the case of a man named Alcock, who was admitted under my care in 1836, for a similar injury of the ileum, and who survived the accident no less than eight days.

REMARKS.—This man, it seems, then, met with a fall, and received, according to his own statement, a blow on the abdomen; but he had had likewise a quarrel with his wife, which he kept concealed, and in which, as he was going to strike her, she put out her foot, and he received something like a kick on the belly. In his illness, perhaps, his conscience pricked him, for he knew that he had been ill-treating the woman, and was probably unwilling to implicate her in the consequences of the transaction. Hence, I suppose, the false account which he gave of the particulars of his case, and especially of that part of it relating to the alleged first production of the hernia on the morning of the accident, and from the blow received in the fall against the area steps. Now, although various circum-

stances, as I shall presently explain, led us to feel tolerably certain that the bad symptoms depended upon some lesion within the abdomen produced by the external violence, yet, when the failure to procure evacuations from the bowels had continued beyond a certain period, and the symptoms of peritonitis were getting worse and worse, I deemed it right to question the patient repeatedly concerning the truth of his statement about the hernia being quite a recent one, and its not having existed prior to the morning of the fall, and he as repeatedly affirmed that it was not of longer standing. Under these circumstances it seemed just possible that some part of the bowel might be entangled and strictured within the inguinal canal, or at the inner ring; for, until motions had been obtained, though the parts appeared to be easily reducible, they always protruded again the instant the pressure was removed, and, as we find recorded, no blood was discharged *per anum*, as might have been expected from a lesion of an intestine. The man's false account of himself, and the latter considerations, at one moment led me to think of laying open the inguinal canal; but directly I spoke of an operation the patient's manner at once informed every body who saw him that he had been giving an untrue account of himself, and that he knew that the source of his perilous symptoms was not the hernia.

Gentlemen, were you to meet with such a case again, I would invite your attention to the following points, as calculated to guide you through the difficulties:—

1. The state of the pulse immediately after the accident. Had the case been a strangulated hernia, the pulse might have been at first 80 or 90, and full, but not 130 and remarkably feeble, with coldness of the extremities. In fact, a hernia would not have occasioned the rapid depression of the system, that marks the laceration of some important internal organ.

2. The freedom from tension and severe pain in the tumor was another difference from a strangulated hernia.

3. So was the facility of reduction, notwithstanding the return of the protrusion directly afterwards, until free evacuations from the bowels had been procured.

These, I think, would be the principal points meriting your attention, as forming the basis of an accurate discrimination.

*Considerable hypertrophy of the bursa over the ligament of the patella—Excision of the tumor.*

Mary Lovett, æt. 30, admitted April 18, 1839. About five years ago, she no-

ticed a swelling in front of her right knee, attended with pain, and attributed by her to kneeling a great deal on a paved kitchen. At first she tried leeches; but as she had no opportunity of discontinuing her work, they afforded her but little relief. The swelling soon became larger and harder, and at length was a serious incumbrance to her, rendering her in some degree lame.

On her admission the enlarged bursa was equal in size to an orange, and seemed from its cartilaginous hardness to leave no chance of removal by any other means than the knife. I performed the operation on the 25th of April, making two semilunar incisions, and then dissecting the bursa out. Its deeper part was so closely united to the ligament of the patella as to be, as it were, consolidated with it; and some care was therefore required to avoid wounding the knee-joint. The sides of the wound were approximated with strips of adhesive plaster, and a cold evaporating lotion was applied. No serious constitutional disturbance ensued, and the wound, which did not unite, healed up after a time by the granulating process.

The bursa in front of the ligament of the patella is very liable to inflammation in persons who kneel a great deal on hard surfaces, as is the case with housemaids employed in scouring floors. In most instances, the first effect of the inflammation is to cause an increased secretion of the synovial fluid within the bursa. In other cases, the bursa becomes distended with turbid serum, in which are flakes of coagulated albumen, or perhaps of fibrin. Occasionally the inflammation advances to suppuration. Sometimes the membrane of the bursa becomes thickened and converted into a gristly substance. I have often seen it nearly an inch in thickness. In the specimen before us, removed from Mary Lovett, the bursa is every where transformed into a gristly substance, with the exception of a small portion of its centre, which was cellular, and out of which a small quantity of synovial fluid could be pressed. Now and then the bursa is converted into a bulky mass entirely solid.

When the bursa inflames, an early effect is generally an increase of the synovial fluid in it, and hence a fluctuation is at first perceptible, attended with redness of the skin; but afterwards, as the bursa becomes thickened, the fluid is less perceptible.

It is not my intention, gentlemen, to enter into a description of the treatment of inflamed and diseased bursæ, as they present themselves in the stage of acute inflammation, or of abscess, or of chronic

inflammation. The case before us only exemplifies what may be done when a bursa is converted into a tumor with very thick sides, or even into a perfectly solid mass, and the patient is lamed, and rendered incapable of earning a livelihood so long as the tumor remains. I would not, however, recommend you to attempt the excision of diseased bursæ, unless the inconvenience from them be truly great, and they resist other means of cure. Operations of this kind have sometimes been followed by a fatal attack of phlegmonous erysipelas. The constitution you have to deal with, as well as the annoyance of the tumor, must therefore also be considered. Diseased bursæ cannot prudently be removed if they envelop tendons, or communicate with the cavity of a large joint. The bursa must be a superficial one to justify the operation.

The bursæ mucosæ appear to be easily reproduced, and are well known to be readily formed, as occasion requires, wherever parts of the body are subjected to habitual or long-continued pressure. Sir Benjamin Brodie lately mentioned to me a case, in which he extirpated a large diseased bursa situated in front of the knee; and, not long afterwards, the same patient presented herself at the hospital with another bursa in the same situation, and nearly as large as that which had been removed.

#### CLINICAL REPORTS

OF

#### DIFFICULT CASES IN MIDWIFERY.

By ROBERT LEE, M.D., F.R.S.

Physician to the British Lying-in Hospital, and  
Lecturer on Midwifery at St. George's  
Hospital.

#### FIFTH REPORT.

[Continued from page 12.]

#### *Cases of Distortion of the Pelvis in which Premature Labour was induced.*

CASE CXXVI.—On the 3d July, 1828, I was requested by Mrs. Phillips to deliver Mrs. Rodwell, a little deformed woman, 26 years of age, residing at No. 21, Princes Street, Drury Lane, who had been in labour with her first child upwards of twenty hours. The umbilical cord was hanging out of the external parts and did not pulsate. The right foot was in the vagina, and the head over the brim of the pelvis, and so firmly fixed in that situation, that by no force which I could exert upon the left leg

could the nates be brought into the pelvis. The pains were feeble and the orifice of the uterus but partially dilated. The outlet cavity and brim of the pelvis were all very much distorted. Finding it to be impossible to bring down the breech of the child, or press back the head, I performed the operation of craniotomy, and it was not till the greater portion of the bones of the cranium had been removed with the crotchet, that I succeeded in dragging down the trunk and superior extremities of the child. When this was done, the crotchet was passed up, and its point fixed on the base of the skull, and the head drawn into the cavity and through the outlet of the pelvis. Dr. Stephen Hall was present at the delivery, which lasted from ten at night till two o'clock in the morning.

The tuberosities of the ischia were not more than an inch and a half asunder, and the distance from the promontory of the sacrum to the symphysis pubis was under three inches.

This patient had a severe attack of uterine inflammation after delivery, which required copious venescence. In ten days she had nearly recovered her usual state of health.

CASE CXXVII.—In 1829, about 15 months after this, Mrs. Rodwell being in the 7½ month of her second pregnancy, I brought on labour by detaching the membranes with a bougie from the lower part of the uterus. Labour came on 60 hours after this separation had been made. The head of the child presented, but it could not be pressed through the brim of the pelvis, though she was left 48 hours in labour. The head was easily extracted with the crotchet after perforation, and she speedily recovered.

CASE CXXVIII.—In 1830 the same patient had premature labour induced a second time at the 7½ month of her third pregnancy. A superior extremity presented, and the operation of turning was performed with great difficulty. After the child had been turned, the head could not be brought through the brim of the pelvis, till perforated in the back part, and strong traction employed with the crotchet.

CASE CXXIX.—I induced premature labour a third time in 1831, when Mrs. Rodwell was at the 7½ month of her next pregnancy. The nates presented, and after the trunk and extremi-

ties of the child had been extracted, the head could not be drawn through the brim of the pelvis without the operation of craniotomy. This was performed with the perforator and crotchet, as in her first labour.

**CASE CXXX.**—On the 5th October, 1832, Mrs. Rodwell being in the 7½ month of her fifth pregnancy, I passed up an elastic catheter into the uterus and detached the membranes all round from the cervix. No pains having been felt, three days after I separated the membranes still more extensively. This was followed by a considerable hæmorrhage from the uterus for several hours, but no labour pains. The following day she appeared much exhausted, but there were no labour pains. I then perforated the membranes, and the liquor amnii began to escape and labour pains came on soon after. In the evening the pains were strong, the os uteri was widely dilated, and it was ascertained that the nates presented. The labour was allowed to continue for several hours, till it became certain the nates would not pass without assistance, and they were then extracted, and also the trunk and superior extremities. The head, however, would not follow, though I pulled strongly upon the neck. The perforator and crotchet were employed, and the delivery was at last effected, but death took place five days after from uterine phlebitis.

**CASE CXXXI.**—On the 17th January, 1830, I was called by the late Mrs. Dobson to deliver Mrs. Jarvis, æt. 30, residing at No. 6, Gough Street, Clerkenwell, who had been forty-eight hours in labour. The pelvis was greatly distorted, the whole head of the child above the brim, and the os uteri not more than half dilated. The pains had nearly ceased, and she was quite exhausted. The perforator was conducted to the head, along the inside of the fore and middle fingers of the left hand, and with these the os uteri was protected from injury, while the opening was being made. The crotchet was then introduced, through the opening, within the head, and the brain broken down, and a quantity of it discharged. I found it impossible to lay hold of any part of the head without the craniotomy forceps, from the distorted state of the pelvis and undilated state of the os uteri. More than

three hours elapsed before I succeeded in dragging the head with the crotchet into the cavity of the pelvis, and not until the point of the instrument was passed up and fixed on the outside of the head behind the jaw. The bones of the upper part of the head were all torn to pieces, and the fingers of my left hand much injured before the delivery was effected. The placenta came away in half an hour, and the patient recovered as if the labour had been natural.

Mrs. Jarvis was a native of Manchester, and when young had spent several years in one of the cotton manufactories of that town. She married at 20, and had given birth to three living children at the full period without assistance. During her fourth pregnancy, she suffered much from pains about the sacrum and ilia, and became unable to walk.

**CASE CXXXII.**—On the 11th July, 1832, I was requested by Mr. John Prout, surgeon to the British Lying-in Hospital, to see Mrs. Jarvis, who had again become pregnant, and was in labour at the full period. Labour commenced at 2 o'clock in the morning of the 11th July, when the liquor amnii was discharged. In the evening Mr. Prout saw her for Dr. Golding, and from the distorted state of the pelvis he found it impossible to reach the os uteri with the finger, and thought delivery could never be accomplished but by the Cesarean operation. At eleven o'clock at night I saw her with Mr. Prout, but the os uteri could not be touched with the finger, and the nature of the presentation could not be ascertained. The pains being weak and irregular, and there being no reason for immediate interference, we resolved to leave her without assistance during the night, hoping that the orifice of the uterus and presenting part of the child would come into a more favourable situation. At eight A.M., 12th July, we found that there had been strong pains during the night, but neither the orifice of the uterus nor presentation could be felt. In the course of the day Dr. Golding saw her with us, and it was then ascertained that the orifice of the uterus was considerably dilated, and that the head of the child presented. The head was immediately perforated, and the brain destroyed. Fourteen hours after, when the bones of the head had been a little

squeezed into the brim of the pelvis, Dr. Golding passed up the crotchet between the uterus and head, and fixing its point in one of the orbits, succeeded in dragging the head through the pelvis.

She recovered as favourably as she had done in 1830. She did not suffer from pains about the pelvis after this time, and was able to walk about. There was no distortion of the lower extremities, or of any other part of the body.

**CASE CXXXIII.**—In the month of June 1833, when the same patient was near the end of the 5th month of pregnancy, I attempted to induce abortion by perforating the membranes with a slender silver catheter. The first attempt was unsuccessful from the firmness of the membranes, but the second trial made a week after was speedily followed by the escape of the liquor amnii, and in eight days, by the expulsion of the embryo, without artificial assistance.

**CASE CXXXIV.**—On the 12th Feb. 1835, I induced premature labour in the same patient at the commencement of the 7th month of pregnancy. Thirty-two ounces of liquor amnii flowed through the silver catheter with which I punctured the membranes. The fœtus was expelled without artificial assistance, but its head was squeezed so as to be quite flat on the sides. Mr. Williams, of Calthorpe Street, and Mr. Rumsey, of Beaconsfield, were present.

I may here remark, that in no case of distortion, however great, can it be necessary to induce premature labour before the end of the 5th month of pregnancy, when the fœtus is so small and soft that it can be easily extracted. The length of the cervix uteri before this period must render it both dangerous and difficult.

**CASE CXXXV.**—On the 19th Jany. 1836, when the same patient was at the end of the 6th month of pregnancy, I endeavoured to induce premature labour by puncturing the membranes. The os uteri was, however, so high up, that I could not reach it with the point of the finger, or introduce the catheter so as to perforate the membranes.

On the 12th Feb. 1836, I renewed the attempt, but again failed, and partly in consequence of the fore-finger of my left hand being still nearly deprived of sensation and the power of motion, from

a dissection wound, followed by deep-seated inflammation of the joints.

I resolved to try the effects of ergot of rye, and gave five grains every four hours for several days. On the 18th, Mrs. Jarvis informed me that she had felt pains in the back, and down the thighs, for about ten minutes after taking each powder of ergot, but that no other effect had been produced by them.

The ergot was continued every three hours during the day till the 23d, when pains like those of labour came on, but they gradually ceased, and the ergot was discontinued, in consequence of the sickness and vomiting it produced.

On the 28th, the ergot was again tried, but as it produced nothing but violent sickness, she refused to continue its use any longer.

On the 14th of March, another attempt was made to perforate the membranes with the instrument invented by Mr. Holmes for the induction of premature labour, but this was also unsuccessful, in consequence of the instrument not being sufficiently curved.

On Thursday, the 24th of March, I passed up into the uterus a stiletted silver catheter, much more bent, which had been made for the purpose, and with this the membranes were easily perforated. The liquor amnii immediately after began to escape, and labour pains commenced the following day. Friday, 25th, the pains continued feeble and irregular during the Saturday, Sunday, and Monday, and on the Tuesday they became strong and regular.

At 6 o'clock in the morning of Wednesday, the 30th, the os uteri was thick and unyielding above the brim of the pelvis, and very little dilated. The presentation could not be ascertained. The pains continued strong and regular. Mr. Simpson, of Gray's Inn Lane, took  $\text{ʒviii}$ . of blood from the arm and gave 40 drops of laudanum. At this time I feared that it would be necessary to have recourse to the Cæsarean operation, to prevent her from dying undelivered.

At 4 p. m. the pains continued; the os uteri was much more dilated, and I ascertained that the nates presented. I immediately resolved to attempt delivery, by passing the crotchet through the anus, completely within the pelvis of the fœtus, fixing it upon the bones, and extracting. This succeeded, and the pelvis and lower extremities were de-

livered without much difficulty, and a strong tape was passed around the body of the child. The abdominal and thoracic viscera were then drawn out with the crotchet, and the upper extremities brought down. The fore and middle fingers of the left hand were then slid along the back of the child, and pressed forward till they touched the occiput. The perforator was then passed up to the occiput, and a free opening made in it. The crotchet was next passed up, and its point forced through the opening, fixed on the base of the skull, and strong traction made for some time. At last I succeeded in extracting the head, with the bones all crushed together.

After this severe and tedious operation she was left in a very exhausted state, and died the following day, with vomiting and other symptoms of ruptured uterus.

On examining the body after death we found the muscular coat of the anterior part of the neck of the uterus lacerated. The pelvis was removed, and is now in the Museum of St. George's Hospital. Its brim, cavity, and outlet, are all much distorted; the last lumbar vertebra occupies the usual situation of the base of the sacrum, which is pressed down into the cavity; the bones of the pubis have been forced together so as nearly to touch each other, and give to the brim of the pelvis a cordiform shape. On the left side, a line drawn from the middle of the last lumbar vertebra to the ilium, behind the acetabulum, measures one inch and a half; on the right side, a corresponding line measures only an inch and a quarter; from the middle of the last lumbar vertebra to the bones of the pubis the distance is an inch and three-quarters.

At the outlet, the tuberosities of the ischia are only three or four lines asunder, and the arch of the pubis does not exist; the lower extremities of the sacrum and coccyx pass horizontally forward, so that the apex of the latter bone is only two inches and three lines from the point where the tuberosities of the ischia nearly meet.

This is the only case of distortion from malacosteon that I have met with in practice, and the softening was entirely confined to the bones of the pelvis.

In reflecting on this case I regret

extremely that I placed the slightest dependence on the ergot of rye, and that I had not taken means to ensure the perforation of the membranes at an earlier period, which would have prevented all the evil consequences that followed.

CASE CXXXVI.—On the 30th Aug. 1836, I was requested by Mr. Wise, of Wardour Street, to deliver a woman, named Robinson, 24 years of age, residing in Princes Court, Newport Market, the bones of whose pelvis and lower extremities were much distorted with rickets; she was at the full period of her first pregnancy, and had been in labour many hours; the cord was hanging out of the external parts without pulsating; the head was entirely above the brim of the pelvis, and the os uteri was about half dilated, and its edge thin and soft. As the sacro-pubic diameter scarcely exceeded two inches, and the outlet of the pelvis was also much contracted, I immediately perforated the head. The crotchet was then employed to extract the head, but after a time it was laid aside, in consequence of the bones being torn extensively, and the impossibility of fixing its point on any part of the inside of the skull so as to obtain a secure hold. With the craniotomy forceps I laid hold of one of the parietal bones and the integuments covering it, but in a short time these came away, leaving the greater part of the head still above the brim; the forceps was reapplied, but though I exerted my whole force in dragging down the head, it would not pass, and I began to fear that I would not succeed in completing the delivery. By introducing all the fingers of my left hand into the vagina as far up as possible, and directing the forefinger on the outside of the head, I was able to feel one of the eyes. I passed the point of the crotchet into this orbit, and getting the fore and middle fingers of the left hand on the inside of the skull, and with this hold I soon drew the head into the cavity of the pelvis. The head would probably never have been extracted in this case with the crotchet, had not its point been carried up on the outside and fixed in the orbit.

CASE CXXXVII.—On the 1st October, 1837, when this woman was at the end of the seventh month of her second pregnancy, I induced premature labour. She

was left long in labour, but the head would not pass till it was perforated. The extraction of the head was an easy operation.

[To be continued.]

## ON VACCINATION.

*To the Editor of the Medical Gazette.*

SIR,

It may, perhaps, be remembered by some of your readers, that, about a year ago, I was induced, from circumstances then stated, to publish in your journal a brief outline of some opinions I had entertained regarding the origin of the vaccine disease. From time to time since that period I have repeated my experiments, inoculating with the small-pox virus both the cow and calf—upon the udder, the teat, under the tail, and within the ear, without, however, being able to obtain the expected lymph. At the last meeting of the British Association I brought the subject before the Medical Section, in a paper “Upon the Cause of the Increase of Small-Pox, and of the Origin of Variola-Vaccinia.” I was then informed by Dr. Baron that Mr. Ceely, of Aylesbury, had lately obtained what I had desired to procure, by inoculating a cow with the variolous matter upon the labiæ pudendæ, and that, from the vesicle of lymph produced, he had vaccinated several children with perfect success. The correctness of my theory is thus established by experiment; but some may perhaps say that this was only practically acting upon Jenner’s theory: now Jenner’s theory was, that “cow-pock was probably coeval with the brute creation;” whereas I considered it probable that cow-pox originated in small-pox, *i. e.* that variola-vaccinia sprung from the human variola.

The reasons I had for forming this opinion may be thus briefly stated:—Previous to the great discovery of Jenner we know that small-pox prevailed to an alarming extent, and we are also certain that the vaccine disease was much more common amongst cows, at that period, than it is now. Looking at these facts thus placed together, one was more apt to view them in the relation of cause and effect than as a matter of mere accident. We have only to be-

lieve the accounts recorded of this wide spreading pestilence, and readily admit the ease with which the virus might be carried from, and by, one living being to another. But further, we have generally been led to believe that two *dissimilar* contagious irritations could not go on *together* in the system at the same time; but several cases are reported, by different authors, of variola and vaccinia running their course together: not a few of such cases came under my observation at Ripon during an epidemic which prevailed there in 1837, reports of which I read at the medical section of the Association. If, then, such cases do occur, and if there be any truth in the preceding axiom, it appeared to me that the two diseases, variola and vaccinia, could not properly be considered dissimilar—which proposition has assumed the appearance of a certainty by the late experiments.

Having, then, established this point, the discovery is capable of becoming in an eminent degree beneficial to man. Suppose, for instance, that small-pox broke out epidemically in a town or village isolated, or cut off from communication with other towns or villages by any imaginable cause; that the disease was raging fearfully around, and every day increasing the number of its victims, whilst the prophylactic had entirely died out of use, and disappeared; in such a case all that would be necessary to stay the plague, would simply be to take the variolous matter from off a patient, who might even be dying of the disease, and inoculate a cow upon any of the mucous surfaces, and thenceforth obtain a plentiful supply of genuine preventive vaccine lymph.

I had intended to have said a little upon the similarity of the two diseases, variola and varicella, and to have shown that the same cause which produces small-pox during a variolous epidemic in the unvaccinated, may and does give rise to chicken-pox in the vaccinated; but I would rather, at the present critical period, when people are almost entirely neglecting vaccination, and when as rapidly, small-pox, in all its loathsomeness, is stealing upon them, and when the number of deaths from this disease alone, within the last year, is almost inconceivable, I would rather, I say, call upon our medical brethren throughout the kingdom, with one

voice to petition the government to enforce (as is done abroad) not only the vaccination of every child born in these realms, but the re-vaccination of every man in the British service; for it is expedient for the public good that a legal obligation be laid upon the nation.

In concluding, I have to offer an apology for having occupied so large a space in your valuable journal, but the importance of the subject merits our consideration, and must alone be my excuse.—I am, sir,

Your obedient servant,

JAMES INGLIS, M.D.

Halifax, Sept. 24, 1839.

## DIAGNOSIS OF THORACIC DISEASES.

*To the Editor of the Medical Gazette.*

SIR,

THE histories of two cases of intrathoracic disease diagnosticated during life, and verified by post-mortem examinations, are exceedingly interesting in many points, and especially serve to show the possibility of medical men making the diagnosis of phthisis in many cases where it either does not exist alone, or is not even present at all. In some cases we readily admit the utter impossibility of arriving at a true diagnosis, but on the other hand there are a number of cases in which the exact nature of the disease affecting the lung can be prognosticated, even in the case of tumors affecting the organs of respiration, from collateral circumstances, aided by the physical signs; as the following case illustrates:—

J. B—, æt. 22, a man of small stature, blue eyes, auburn hair, and exceedingly fair skin, applied for medical advice, in consequence of his not being able to perform his avocations as vocalist, owing to hoarseness and roughness of his throat. He acknowledges having led, for the last six or eight months, a very dissolute life, seldom or never being in bed before four o'clock in the morning; has frequently been exposed to the vicissitudes of temperature, drank hard, and has been in every way careless of his health. About six months ago, he observed a swelling under the angle of the submaxillary bone,

which he took no notice of at first, but becoming painful, he took the advice of his medical man, who applied an ointment of some kind, but without relief. The tumor gradually enlarged, and at length suppurated, giving exit to about an ounce of pus. His voice at this time was only a whisper; his throat became painful when pressed, and a very troublesome cough, accompanied with a rosy expectoration, disturbed his repose. Did not sweat at night; now and then had slight shivering; bowels rather too free, but cannot recollect the exact number of evacuations passed daily. Began to loose flesh and strength very fast. He gradually grew worse, when, two months ago, I for the first time saw him. He was then greatly emaciated; countenance expressive of great suffering; speaks in a hoarse whisper; ulceration of throat extensive. Tongue furred; complains of great thirst.

His breathing is remarkable, and accompanied with great muscular exertion, and, if I may be allowed the expression, instead of appearing to proceed from the mouth, seems as if it proceeded immediately from the upper part of the sternum, and his voice, when speaking with the slightest effort, produces the same effect. Says he wishes to cough, but cannot. On percussion of the chest it gives a clear sound everywhere: on the application of the stethoscope the following phenomena are audible. Under the left clavicle the respiration is decidedly cavernous, and occasionally there is a loud gurgling râle. Over the whole of the inferior portion of the lung respiration is exceedingly feeble: at the apices of both lungs the voice is resonant, not, however, amounting to pectoriloquy. The same phenomena are audible on the right side, but with this exception, that the respiration is louder. On listening over the sternum, the tracheal respiration is exceedingly loud, and seems to come up into the stethoscope. Examining along the trachea the same fact is observed, accompanied with a slight mucous râle. The place where the tumor originally was still discharges a quantity of puriform matter. At my request he tried to swallow a bit of bread, but complains of great pain in doing so, referred to a spot pointed out by him immediately behind the sternum,

and observes that he experienced the same difficulty in swallowing liquids, and thinks at times that he is choking. Heart's action not very vigorous, and the sounds are heard distinctly at the supero-posterior part of the right lung. Pulse 100, small; does not sweat; has no diarrhoea at present; spat up some blood mixed with mucus; cough very short, but shrill; cannot lie with his head low, in consequence of this feeling of suffocation. He was ordered Inf. Rosæ c. Acid. Sulph. Dilut., and a pill of Ext. Conii and Ipecac. at bed-time, and Chlorid. Sodæ gargle for the throat. Arrow-root diet. As, however, was fully expected, he grew rapidly worse, and died at the end of six weeks from his first attack.

**OBSERVATIONS.**—That the unfortunate being, whether the subject of phthisis or not, was beyond all medical aid, did not admit of a doubt, so that our treatment was only palliative, and in this one respect the case does not possess much value: it is, however, only in a pathological point of view that we lay it before the reader. If, then, we examine carefully into the man's history, and couple this with the facts derivable from the stethoscopic examination, we must, I think, acknowledge, that the existence of *uncomplicated* phthisis was exceedingly doubtful. We had, on percussion, a decidedly clear sound, especially over the left lung. This certainly did not indicate tubercular deposition. There was evidence of cavities in the upper portion of the same lung, but then they were not necessarily tubercular, and the feebleness of respiration led us to suspect emphysema. On the other hand, we have a certain amount of dysphagia, and that almost indescribable and peculiar stridulous respiration which has been designated, I think very properly, by Dr. Wm Stokes, as the "stridor from below;" and we also had, in this case, evident disease of the glands about the neck. Add to this the total inability to cough, not forgetting the loss of voice, which, however, might in some measure be accounted for by the ulceration of the throat, and I think there is but one affection under which we could have placed the disease; and accordingly the following diagnosis was made:—In all probability the man has tubercle, but that he has a tumor of some kind com-

pressing the trachea I think almost evident. He has emphysema of the left lung in its inferior portion, and certainly the signs of cavity, but whether the result of the softening of tumors, or of tubercle, is a matter of doubt. This diagnosis being made, we were naturally anxious to obtain a post-mortem examination, which we were fortunate enough to succeed in.

*Examination 12 hours after death.*—Exterior: Body exceedingly emaciated. No signs of putrefaction as yet.

*Interior.*—A section was made from upper part of cervix to umbilicus, and the viscera carefully removed. The lungs adhered firmly to the pleura by many points, in the cavity of which there was no effusion. The trachea, including the glottis, was now cut away, together with the lungs, and, on inspection, present the following interesting appearances:—There is intense tubercular deposit throughout both lungs; indeed so much so as we have ever seen in the worst cases of phthisis. The lower lobes of left lung are emphysematous: these small cavities exist in the upper portions of both lungs. On examining the trachea, we discover a large tumor (evidently a bronchial gland), filled with a soft cheesy matter, lying on the right side of the trachea, just as it is giving off the right bronchus. This tumor is the size of a hen's egg. The upper portion of the trachea was much affected by ulceration. These are the only particulars worth relating.

It has been seen that in this case at least a successful diagnosis has been made; but there are one or two circumstances deserving of especial mention, and which afford, we apprehend, a tolerably useful guide, when taken in connexion with others, in cases of compression of the trachea. These are, the character of the respiration, and the peculiar efforts which the sufferer makes in performing it; for instance, in mere ulceration of the trachea, although we may have loss of voice, and refer this morbid state to the ulceration of the air and vocal tube, nevertheless the respiratory effort is performed quite differently from what we observe it to be in cases of compression. In this latter case we have the "*vis medicatrix nature*," if I may be allowed the expression, dictating to the parts of the body concerned how to obtain relief; accordingly we find the individual

opening his mouth, the muscles of his neck contract forcibly, and he raises his clavicles and shoulders, as if conscious that by this means he effected a partial removal of the cause of obstruction to the passage of air. Now, as before observed, we do not have these actions produced in cases of mere ulceration of the trachea; and although the breathing be harsh and the voice hoarse, yet it possesses of itself sufficiently distinct characteristics. We will now proceed to the next case.

P. O'H—, æt. 30, has been accustomed to drink rather freely of whiskey, keep irregular hours, and lived on poor diet. His trade, as a blacksmith, exposed him to sudden changes of temperature. His family have been all healthy persons. About three months ago, after a hard day's work, and whilst sweating profusely, sat down in a public-house, with his chest exposed, drinking ale and whiskey. Soon after his return home, he was seized with shivering, pain in head and loins, and the next morning was so stiff in his limbs, and felt so generally ill, that he was forced to keep his bed, which he has never left. Three weeks ago he applied to me for advice, by the request of his medical friend, with the view of confirming the opinion that the man had phthisis. When I saw him, he presented the following condition:—Greatly emaciated, and appears the wreck of a very muscular man. Countenance expressive of great anxiety; respiration performed with great muscular exertion; voice exceedingly hoarse. The chest sounds every where well on percussion: on applying the stethoscope, the following signs were audible:—Mucous r  le in lower portion of left lung, and distinct gurgling in the upper part of same lung; resonance of voice; respiration feeble; general signs of bronchitis in the right side. On applying the stethoscope over the upper part of sternum, the respiration is exceedingly loud, harsh, and attended by a whizzing sound, on listening without the instrument at some distance from the chest—the peculiar “stridulous breathing,” or stridor from below, of Dr. Stokes. Complaints of great pain on swallowing, referred just below the upper portion of sternum; is unable to lie down, and maintains constantly the semi-recumbent position. Sweats at times profusely. Bowels tolerably

regular; is much annoyed by a short, troublesome cough, accompanied with very little expectoration.

Inf. Ros   c. Acid. Sulph.

It would be mere repetition to recount his symptoms daily: he gradually grew worse, and sunk on the second week after I saw him.

*Examination.*—There is not a trace of tubercle in either lung. On the left, and in upper lobe, there are five tumors, filled with cheesy matter, and a larger one in a suppurated state. Immediately under the clavicle in the right lung, there is a small cavity in the superior lobe, and eight or nine small tumors, about the size of hazel nuts. At the root of the trachea, immediately above its bifurcation, there are five enlarged glands, filled with a similar matter as those of the lung, about the size of ripe walnuts, completely encircling the trachea: one of them broke in extracting the parts. It was very much like a cyst, its coats thickened, and by no means vascular; internally it had very much the appearance of an aneurismal sac, thickly studded with atheromatous deposit. On opening one of them it was almost solid, and appeared as if the tumor was composed of a number of little tumors lying close and accompanying each other. In some of them, softening had commenced in the centre; and, what appeared very remarkable, in many of the small tumors, which, so to speak, formed the large ones, the same circumstance presented itself.

This, I am convinced, is the process observed in the softening of many of these glandular tumors, and that this process does not commence in the centre of the present tumor, but in the centre of the individual small tumors of which it is composed: and this does not form an objection to the well-known fact, that tumors generally commence to soften in their centre; for this, in great measure, depends on the age of the central tumors compared with those of the exterior, and also from compression, and no doubt, in many cases, from a super-secretion of fluid parts in the tumor. We are, however, much in the dark about the true nature of this softening, and are by no means acquainted with the laws which influence the change. I have not unfrequently

seen, in these tumors, certain parts only softened and broken down; and on examining them, have satisfied myself that this change had been effected in one of the smaller tumors. In the case of cancerous deposit in the lung, we have also very frequently the same arrangement; but in this case we actually are able to trace the formation of the large tumor by the accumulation of smaller ones: thus, for instance, the cancerous matter is not deposited in one spot, and so spreads from this common centre, but, on the contrary, different parts of the lung furnish a reception for this new disease, and, by their approximation, constitute a large mass of "cancer of the lung." In the two cases which I have the honour of forwarding you, a similar condition was observed, and our museums furnish specimens of a like nature.

I am afraid that I have encroached already too much on your valuable pages, therefore shall conclude for the present; and if you consider my communication of sufficient importance, shall be most happy to furnish you with some other cases.—I am, sir,

Your obedient servant,

J. B., M.D.

Dublin, Sept. 27, 1839.

## MEDICAL GAZETTE.

*Saturday, October 5, 1839.*

"Licet omnibus, licet etiam mihi, dignitatem  
*Artis Medicæ* tueri: potestas modo veniendi in  
publicum sit, dicendi periculum non recuso."

CICERO.

### A FEW WORDS MORE TO PUPILS.

IN our last article we endeavoured to show our younger readers, that much as the healing art depends on the administration of drugs, and the precepts of hygiene, something more is wanting to make the perfect, or even the tolerable practitioner. This something is a good deportment, without which, and a good temper, the most shining abilities will often be the source of little satisfaction to their possessor. It might seem a work of supererogation to state, that a

medical practitioner ought to have a decent manner, did we not see this essential point so frequently and so grossly overlooked by the friends of the young aspirants to our profession.

When the impartial observer gazes with mute astonishment on the unpollished manner, and wilfully uncouth dress, and hears the slang language of certain students, he is immediately convinced that the unfortunate persons before him are suffering under the influence of a distorted ambition, and that their models of life and conduct, instead of being selected from the class above, are taken from some grade infinitely below them. In many instances, no doubt, the mistaken or sporting student wishes us to suppose that this rough arillus is only superinduced over the natural amenity of his habits, and that he is really a gentlemanly young surgeon, though acting a *Pickwickian* sawbones. But, alas! a censorious world will too often cry out with *Martial*—

"*Pauper videri Cinna vult, et est pauper*\*,."

In such cases the motive savours of the "pride which apes humility," and the mimic would be mortified if he knew the extreme success of his performance. In other instances, the strange exhibition is only a consequence of the imitative faculty natural to man, but so foolishly displayed as to border on the results of simple fatuity.

But we will omit, at least for the present, all further discussion of this and similar points, however important, and give a few hints on the subjects more strictly appertaining to medical studies.

\* A most remarkable instance of this successful aping of vulgarity by a congenial mind was recorded in our Journal about two years ago. A young man of fortune, who habitually associated with his grooms, and dressed as one of them, was taken to be the character he played by the landlord of an inn he frequented; and this theatrical illusion lasted two years. The young man died of drinking.—*MED. GAZ.* vol. xxi. p. 547.

The most obvious, the most necessary, and the most neglected of all rules, is—*let application be steady and regular.* Not only will a greater number of hours be thus assuredly gained for study, but those that are thus employed will be made more profitable. Thus, six hours' study daily for ten days is far more useful than ten hours daily for six days; for though arithmetically they come to the same thing, their teaching power is very different. In the former case the fresh and elastic mind grasps the subject presented to it with all its energies; in the latter, the wearied and flagging attention is ever retreating from the topic forced upon it, and what is nominally study is perhaps more than half dozing or reverie.

As the second rule, we should counsel a very scrupulous attendance on lectures: we much question if many students who have observed this precept have been plucked, or even passed discreditably. Should notes be taken at lectures? Dr. Young is of opinion that where two courses of the same are kind to be attended, it will seldom be advisable to take notes of the first one; so that the mind may be wholly devoted to following and comprehending the lecturer. Perhaps, when only one course is attended, the best plan for a diligent hearer will be to take down only the heads of the lecture; or, if he has a tolerable memory, he will find that this may be done to greater advantage after the lecture; and a few attempts will soon improve his power of recollection. To taking notes of the whole lecture we may apply what Dr. Young says of taking them in short-hand, that "it converts the writer into a mere machine\*;" the gist of the question is lost in the details; or, as the old saw has it, we cannot see the wood for the trees.

To read up to lectures is absolutely

requisite. On two of the most essential subjects, the practice of physic and of surgery, the longest course cannot be considered as more than a sketch to be filled up by the zealous student; and it is well to compare the illustrious dead with the successful living, and know what is counselled in other countries by the great masters of our art.

It must be confessed that what we here advise cannot be done, without unusual powers of exertion, by those who are limited to the minimum of two years and a half; but this is merely a demonstration, if such were wanting, that this period, partly occupied as it is with the study of the ancillary sciences, is insufficient for the practical teaching of our profession.

We are ready to acknowledge also that lectures form by themselves too meagre a system of teaching—a skeleton that wants vitality. Mr. Hamilton, the teacher of languages, says that in his schools boys are taught, while in ordinary ones they are only told to learn. Yet in the most careless academy the boy is taught Horace and Virgil on a more effective system than that on which the pupil learns the practice of physic in our medical schools. He is not merely lectured upon the ancient poets, but made to go through them bit by bit, and show, in some rude fashion, that he understands what he is doing. Now if it shall ever be thought worth while to teach anatomy and physic as accurately as Virgil and Horace, the same plan will be adopted. The pupils will go through the details of anatomy before their teacher, step by step, and lad by lad; and they will treat diseases in the chambers of the sick under the inspection of their instructor and his assistants. Something of the kind is done by the medical tutors, or grinders; but instead of its being hurried over in the feverish manner of their establishments, we would have it quiet, cool, unembarrassed,

---

\* Medical Literature, 2d edit. p. 13.

and prolonged. The anatomy, too, would be illustrated in our scheme by dissections performed by the pupil before the eyes of his teacher, in a manner much more regular and methodical than is at present practised.

Meantime, until this happier era arrives, the student will do well to supply the place of this genuine teaching as well as he can. If he is so fortunate as to have a diligent friend, their reciprocal examinations will be of immense utility; and it is possible that, under favourable circumstances, a class for mutual instruction might be formed. The practice of physic will be learned, in part, by attending the sick poor at their own houses. Such cases are easily procured, but it must be allowed that the pupil's attendance upon them is less satisfactory and less instructive than if his visits were under the tutelage of an experienced practitioner.

It is almost unnecessary to remind the student of a fact which has so often been repeated—that in the practice of surgery he must not expect to meet very frequently with great operations, or striking cases. The majority, indeed, of those whom we are now addressing, will hardly ever perform lithotomy, or remove a limb with the knife; but the minor operations will be their daily work, and their daily bread. We almost feel inclined to repeat the anecdote which we gave on a former occasion, of the foot which, when cleverly bandaged on the continent, walked with ease, but when brought back to England and ill bandaged, could walk no longer. Here is a point well worth attention. Even bleeding is not always performed with the utmost skill; and the student is, perhaps, sometimes perplexed by finding that the veins at the bend of the arm do not correspond with the theoretic standard; the variety of distribution being here considerable. Even the application of leeches, trifling as it may seem, is not with-

out its niceties; and the artifices by which they may sometimes be made to bite when reluctant, are worth attention in practice, though they might not cut a great figure in a dissertation. We will mention only two points more—the treatment of old sores, and introducing the catheter, as among those subjects of lesser surgery which it would seem impossible to have passed over, and yet of which the student who has just got through his examination, is, unfortunately for himself and the public, sometimes practically ignorant.

The study of physiology to a certain extent is absolutely necessary, for without it there is no rational practice of physic. All morbid signs depend for their interpretation on our previous knowledge of the healthy ones. Thus a pulse at 96 is known to be indicative of disease, by our foregone conclusion that 72, or thereabouts, is the pulse of health. The tongue, the skin, and the excretions, can be rightly judged of by him alone who is acquainted with their normal state, and knows, at the same time, what numerous varieties are consistent with tolerable health. But physiology has become so vast and illimitable a science, that the facts immediately available for practicable purposes constitute its smallest portion. It now extends its sway over the whole domain of animal and vegetable life; and a great part of its facts are rather laid up, in the hope of future use, than of immediate profit to the practitioner. Hence, the student limited in means, and confined to the curriculum of two years and a half, must content himself with a scanty taste of this most interesting branch of knowledge. Nay, even those who can afford to dedicate double this time to their education, will find that they cannot devote a sufficient period to physiology, without injustice to their other pursuits. Those who have unlimited time at their disposal, or who have finished their education, without

being obliged to begin practice immediately, may yield to its fascinations, if reputation rather than gain is their goal. The same advice will apply, with still greater force, to microscopic investigations, which are almost solely adapted for those who follow physic as a science rather than a profession.

Of chemistry, botany, and medical jurisprudence, we shall say nothing on the present occasion, excepting that the complete study of any one of them would require as much time as the majority of those whom we now address have to bestow on the whole curriculum. Yet some knowledge of them is required as well in a practical point of view as to maintain the position of the practitioner in society, and prevent his sinking into the rank of a drug-distributing artisan. Our younger readers will have ample opportunities of observing that in social intercourse a constant examination of medical practitioners is going on, and that it will not be prudent in them on leaving the Hall to forget immediately how sulphate of quinine is made. The pupil who is plucked at Blackfriars for not knowing the temperatures of a warm bath, and freezing water, will be stared at over the dinner table if he fails there in the same way.

To conclude, we would recommend the student to follow Cicero's advice, and strive for the first grade of excellence, but to be content if he attains the second.

## CLINICAL LECTURES ON OPHTHALMIA.

BY M. VELPEAU.

*Reported for this Journal, by*  
J. HENRY BENNET, B.L. & B.S.  
Sorbon.

### SEQUELÆ AND COMPLICATIONS OF KERATITIS.

*Flammation.—The cicatrix liable to be rendered opaque by preparations of lead.—Remarks on cauterization.—Necessity of avoiding this when there is acute inflammation.—Delicacy of the operation.—Excision of the injected vessels.—Mode of effecting this.—Perforation and fistule of the cornea.*

Two causes have hitherto contributed to prevent the treatment of ulcers of the cornea being properly understood; first, their having always been considered apart from the inflammatory affection which has caused them, or by which they are accompanied, and secondly, the modifications which they present not having been generally recognized. This manner of viewing ulceration of the cornea has given rise to ideas respecting the treatment of such ulcers which ought not to pass unrefuted. Thus many practitioners consider it advisable to treat these lesions by direct cauterisation, or by the excision of the vascular filaments which are distributed to them. Such measures are sometimes useful, it is true, but not when employed in every kind of ulcer, and in every stage of the affection. Those who indiscriminately advise this plan of treatment, seem not to be aware that an ulcer nearly always arises from keratitis, and that, consequently, if we wish to cure the ulcer, we must first cure the inflammatory affection of the cornea. There are, however, some surgeons, such as Mr. Lawrence, who disapprove of cauterization and excision during the acute period of the inflammation, and recommend antiphlogistic measures to be adopted. Scarpa may be named as one of those who place the greatest reliance on excision, &c.

Ulcers of the cornea oftentimes disappear, even when abandoned to nature, and oftener still under the influence of the treatment calculated to remove the keratitis. As, however, they do not always yield so easily, it is necessary that you should be acquainted with those remedial agents which are more especially directed against them.

When ulceration of the cornea is recent, and accompanied by keratitis, the presence of which is indicated by the vascularity of the sclerótica and conjunctiva, the first thing to be done is to cure the keratitis, as by doing so you generally cure the ulcer also. Should it continue, you may employ calomel in powder, a solution of the sulphate of zinc or of the nitrate of silver. This last preparation is decidedly the most efficacious, and seldom fails. Sometimes, however, even this remedy proves ineffectual; in which case you must have recourse to cauterization, or to the excision of the superficial varicose vessels,

*Ulcers of the cornea. — Different modes of treatment.—Necessity of first curing the in-*

which are sometimes found around the ulcer.

The same plan of treatment is generally successful when directed against the plastic ulcer. In treating this kind of ulcer, it is well to avoid the various preparations of lead, as I have found, by experience, that small particles of that substance employed may be deposited at the bottom of the ulcer, and thus render the cicatrix more opaque. Here, again, if other measures fail, cauterisation or excision of the injected vessels may be resorted to. It is, however, useless to cauterize as long as the ulcer is covered by a layer of lymph, the surface of the cornea being then protected in the same manner as if it were covered by an eschar.

The ulcer requires no special treatment as long as the inflammation of the cornea continues. When that has abated, the astringent collyria should be employed, and if they do not succeed, as is frequently the case, recourse must be had to cauterization with the nitrate of silver. It is, indeed, in this species of ulcer that cauterization is the most efficacious. The cure, however, is seldom radical; there nearly always remains, when the ulcer is deep, a speck which impedes the functions of sight more or less, according to the position which it occupies on the cornea. Excision of the injected vessels evidently cannot be performed in these cases, as it is not by the vessels of the conjunctiva, but by those of the sclerotica, that the partial vascularity of the cornea is kept up.

When the tissue of the cornea has been entirely destroyed, and the membrane of the aqueous humour appears at the bottom of the ulcer, topical remedies have but little influence over the progress of the lesion; general measures, and especially blood-letting, being indicated. I have sometimes, however, in these cases, derived benefit from a collyrium composed of one grain of the sulphate of zinc to an ounce of water with some astringent mucilage. If the internal lamellæ of the cornea protrude, cauterization may be resorted to, but only with the greatest caution. Blisters applied over the eyelids are also occasionally useful. The remarks which I have made on the treatment of the first three species of ulcers will also apply to that of the two latter, as long as they are accompanied by acute inflammation. But when the inflammation has subsided, the treatment is no longer the same, cauterization of the ulcer being scarcely ever attended with beneficial results, and that of the incised ulcer being absolutely prejudicial. The non-success of cauterization, when directed against the incised ulcer, may be easily explained. The in-

cised ulcer forming, as it were, a deep fissure, it is impossible to act on its entire surface with the solid nitrate of silver; and when cauterization is resorted to in any form of ulceration of the cornea, unless the entire ulcerated surface be cauterized the operation merely tends to increase the intensity of the disease. The ulcer being also nearly always situated at the circumference of the cornea, the conjunctiva is generally cauterized at the same time, and its inflammation thereby increased.

To resume: cauterization ought not to be employed when there is acute inflammation of the cornea co-existing, unless it be in those cases in which the ulcer has given rise to the inflammation, or in those in which vessels are seen arising, as it were, from the ulcerated surface. When the inflammation has subsided, cauterization is, on the contrary, in some species of ulcers, the best remedy that can be used, as it destroys the extreme sensibility which always exists when the tissue of the cornea is denuded. For such an effect, however, to be produced, the cauterization must be carefully executed, and this is attended with some difficulty. The photophobia being generally very intense, the patient forcibly contracts his eyelids, so that it is by no means easy to keep them open, or to maintain the eye in the same position. Now when you consider that the slightest motion may cause you to cauterize another portion of the cornea instead of the ulcer, and that, on the other hand, it is indispensable that the entire ulcerated surface should be cauterised, you must certainly agree with me that the operation, slight as it appears, is one which requires great nicety, to be properly performed. When cauterization is resorted to, the entire ulcerated cavity must be touched with a cone of lunar caustic, rounded at the extremity. This must be done very lightly when the ulcer is deep, in order that the remaining layers of the cornea may not be destroyed. Some tepid water must then be poured over the eye, before the patient is allowed to close his eyelids, to prevent the caustic acting on the surrounding tissue. When the cauterization has been effectually performed, the severe pain which the patient at first feels soon subsides, and he then suffers much less than he did before the cauterization. On the third or fourth day the photophobia and epiphora generally return, owing to the falling of the small eschar which is formed, and it is sometimes necessary to repeat the cauterization two or three times.

The only plan of treatment, besides cauterization, which I have mentioned as being specially directed against ulcers of

the cornea, is the excision of the injected vessels. Excision has been often resorted to when it ought not to have been employed, and having then proved rather detrimental than otherwise, has been entirely rejected by most practitioners. Though of little or no use when the vascularization of the cornea is supplied by the vessels of the sclerotica, it may be attended with beneficial results in superficial keratitis, accompanied by inflammation of the conjunctiva, and by injection of the superficial vessels of the inflamed membrane. The vessels must be seized with a small pair of forceps, and are then excised with ease. Sometimes, when the cornea is covered with small ulcers, the principal vascular filaments are given off from the conjunctiva, in which case their excision is indicated. Some authors have proposed the excision of a circular portion of the conjunctiva. This proposal, though favourably received by a few practitioners, has not met with the same reception from others. The remarks I have just made will equally well apply in this instance. If the keratitis is kept up by the conjunctival vessels, excision of a portion of the conjunctiva is likely to prove efficacious; but if it is kept up by the deep-seated vascular layer, the operation cannot be of much avail. You must also bear in mind that excision of a part of the vascular mucous membrane may, as I have already told you, be followed by disagreeable consequences.

Ophthalmologists have advised that the surface of the ulcer be scraped or excised, to prevent the formation of an albugo or a leucoma. This plan of treatment is evidently applicable to those ulcers only on which there exists a layer of coagulable lymph, and even then I can hardly say how far it would prove advantageous. Such an operation would also require such great manual dexterity, that I do not think many surgeons of our own times will feel inclined to perform it.

Ulcers of the cornea constitute one of the most frequent complications of keratitis; it is, therefore, of great importance that the treatment should be thoroughly understood, and I should advise you always to keep in mind the principles I have just laid down. If you adopt them in your practice, you will scarcely ever see an ulcer followed by perforation of the cornea and loss of the eye.

*Perforation and fistula of the cornea—Hernia of the iris.*

Ulceration of the cornea sometimes leads, as I have already told you, to the perforation of that membrane; but this accident is most frequently observed in the

purulent ophthalmia of new born children, and in the Egyptian or gonorrhoeal form of purulent ophthalmia. A portion of the cornea, nearly always situated in the centre, softens, assumes a yellow tint, and rising above the level of the surrounding parts, at last bursts. The perforation is sometimes sufficiently large to allow the crystalline lens to pass; when this is not the case the tumors of the eye only escape.

It is a fact worthy of notice, that perforation of the cornea may be caused by inanition. M. Magendie found that it soon occurred in dogs, to which no nutriment was given, or that were fed on sugar. I have several times unobserved the same phenomena in patients who had been long deprived of aliment, or who had been exhausted by repeated blood-letting. In this case the symptoms which precede the perforation differ, in some respects, from those which are observed when it occurs in purulent ophthalmia. A circumscribed portion of the cornea gradually becomes opaque, then softens, for it can hardly be said to suppurate, and perforation takes place, without its having been preceded by any rising or swelling of the membrane. As the perforation may be small, and is not always situated opposite the pupil, it is not necessarily followed by loss of sight.

Every possible measure, calculated to prevent the occurrence of such an accident, must be adopted by the medical attendant, for when it has taken place, a palliative treatment only can be employed.

Owing to the firm and resisting nature of the cornea, a perforation of that membrane may remain open during a variable period, and thus deserve the name of a fistula; fistulous openings on the cornea are, however, extremely rare, I have only met with seven or eight instances during the entire course of my practice, and they are only observed when the perforation occupies the central portion of the membrane. Indeed, it is only in this region that the opening can, owing to the absence of the iris, remain free. One of the most remarkable cases of this kind that I have seen, was that of a young girl affected with hydropthalmia. The cornea being greatly distended paracentesis was performed, and the puncture remained fistulous during eighteen days. I also remember another case in which the perforation, caused by inanition, remained fistulous during three weeks.

Generally speaking, after perforation of the cornea, the iris being pushed forward, either simply closes the opening, or otherwise projects, so as to form a small tumor on the outer surface of the cornea. In some instances it is not the iris but the vitreous humour which protrudes; and

when this is the case, the tumour presents the appearance of a small transparent vesicle.

Various names have been given to the hernia or prolapsus of the iris; thus it has been alternately denominated, *myocephalon*, *clavus*, *staphyloma of the iris*, &c. In the days of Galen, names were coined to represent the slightest peculiarity observed in a disease. The cause of this extreme diversity of nomenclature is partly to be found in the fact that medicine was then, in a great measure, in the hands of specialists, and when a man of powerful intellect is shut up in a small circle, his mind soon feels the want of aliment, and he, consequently, endeavours to extend the limits which are traced around him. Many plans of treatment are recommended against this affection, most of which are by no means so efficacious as those with whom they originated supposed them to be. Belladonna has been much lauded by some practitioners; as, however, it can only be useful when the prolapsus is quite recent, and when no adherence has yet been formed between the iris and the cornea, its utility becomes very restricted. The action of belladonna is purely mechanical; by dilating the membrane, it may, if the perforation be a certain distance from the circumference of the cornea, draw out of the opening that portion of the iris which protrudes. When the hernia of the iris passes the level of the cornea, it becomes a source of irritation to the eyelids, owing to the continual friction that takes place, and may occasion an exacerbation of the inflammation of the cornea, or its renewal, if it has been previously subdued. The exposed portion of the iris also often becomes the seat of great irritation, and gives rise to vegetations of various forms. When there is great inflammation existing, emollients and antiphlogistics should be employed; if, on the contrary, there be but little inflammation, the most efficacious plan of treatment which can be adopted is cauterization with the nitrate of silver: great care must be taken, in performing this slight operation, not to cauterize the cornea or the conjunctiva, as the inflammation would be thereby much increased. When the cauterization is properly executed, the patients generally feel great relief; but as it is extremely difficult to avoid injuring other parts of the eye, I would advise you only to resort to cauterization when it is indispensable. The astringent collyria usually employed in ophthalmiæ, may sometimes be used successfully. In one or two instances, in which I had prognosticated an aggravation of the malady, unless cauterization were resorted to, the patients got well in the course of a few months,

although astringent collyria only had been employed. Since then I have, several times, allowed the disease to take its course, without attempting to cauterize, and the patients have likewise got well. You see, therefore, that we may occasionally temporize when the ophthalmia is slight, and there is no fear of suppuration and sloughing of the cornea. This, however, only applies to cases in which the perforation of the cornea is small; when it is large, and the prolapsus of the iris is considerable, cauterization must be resorted to as soon as the inflammation has subsided.

## LUNATIC ASYLUM OF ABERDEEN.

REPORT FOR THE YEAR ENDING 30TH  
APRIL, 1839.

[For the London Medical Gazette.]

TABLE I. OF THE NUMBER OF PATIENTS ADMITTED DURING THE YEAR.	
Number of Patients in the Asylum	
1st May, 1838	116
Admitted between 1st May, 1838, and 1st of May, 1839	53
	<hr/> 169

Whereof were considered curable (of the former number).	13
Do. (of the latter number),	22
	<hr/>
Total number of supposed curable cases during the year,	35

TABLE II. OF RESULTS.	
Dismissed between 1st May, 1838, & 1st May, 1839. Cured,	20
Do. do. do. Improved,	7
Do. do. Unimproved,	2
Dead,	14
	<hr/>
Total number removed from the Asylum during the year,	43
„ remaining in the Asylum 1st May, 1839,	126
	<hr/> 169

The number of cases admitted into the Aberdeen Asylum during the last year, amounting to 53, has been larger than during any former year. This increase may be accidental; but it is more probable that insanity is not only more commonly met with in society, from the growing nature of the population, but that it is so relatively, from the operation of that law peculiar to it, with a few other dis-

cases, viz., its hereditary transmission from one generation to another. And the law just alluded to is, perhaps, stronger, in regard to insanity, than almost any other malady. As of late years much improvement has been effected (both at home and abroad) in regard to the treatment of a disease which used, at one time, to be considered beyond the reach of medical science, so there is reason to hope this improvement may continue to keep pace with its growing frequency; and thus, in the event of insanity becoming more common, it will also be more frequently cured. Considering also the gradual change taking place in the public mind, in regard to the subject of insanity in general, we confidently trust that, ere long, that foolish prejudice will be got rid of, which, by leading, in many instances, the friends as well as the patients to conceal the malady as long as possible even from the physician, throws one of the greatest barriers in the way of the recovery of the insane; the early and curable stage being allowed to pass without any attempt at rational treatment, or, at best, under the trial of ill-directed and inefficient measures.

TABLE III.

EXHIBITING THE AGES OF THE PATIENTS  
ADMITTED DURING THE YEAR.

	Males.	Females.	Total.
Under 10 years, . . .	1	0	1
From 10 to 19, . . .	1	2	3
„ 20 „ 29, . . .	7	7	14
„ 30 „ 39, . . .	8	5	13
„ 40 „ 49, . . .	3	4	7
„ 50 „ 59, . . .	3	9	12
„ 60 „ 69, . . .	2	1	3
	25	28	53

The first in the preceding table was a boy of only eight years of age, who, along with spectral illusions, exhibited occasional fits of maniacal excitement, and laboured under such weakness of the extremities, as almost amounted to paralysis—the whole being the sequence of an attack of typhus. He, however, speedily recovered, under a course of tonics, combined with sedatives.

Several of those who occupy the opposite extremity of the scale were admitted in a hopeless state of fatuity, conjoined with palsy.

Of the intermediate ages, the largest number was between twenty and forty—a period during which the minds of individuals are generally most agitated by the anxieties and struggles of life,—whereby any latent predisposition to the disease is roused into action.

The disease has assumed its various

modifications in the proportions seen in the following table:—

TABLE IV.

FORM OF THE DISEASE IN THE CASES  
ADMITTED.

	Males.	Females.	Total.
Mania, . . .	5	8	13
Monomania, with excitement, . . .	7	7	14
Monomania, with depression, . . .	5	8	13
Dementia & Fatuity, . . .	7	5	12
Moral Insanity, . . .	1	0	1
	25	28	53

Thus we find that the largest number is of the class styled monomaniacs, although not always in the strictest sense of that term; for when a single faculty of the mind is perverted, the exercise of the judgment is seldom left perfectly free on other subjects: so that the correctness of that view of insanity which renders it necessary to prove that a criminal action committed by a person labouring under a single delusion—a monomaniac,—arose from the delusion in question, in order to free him from responsibility, may be doubted.

The several forms of the disease laid down in the table, offer different prospects in regard to the probability of cure. *Mania* and *Monomania, with excitement*, are most favourable, other circumstances being alike—such as the constitution of the patient, and the duration of the disease. *Monomania, with depression*, is less curable, especially when the delusions are of a religious nature, and accompanied with a propensity to suicide, or arise from a belief in supernatural influence. Delusions of the latter kind, being of a nature not to attract observation, are often entertained in secret by the patient long before they are noticed by friends,—and thus have had time to become, as it were, a part of the mental constitution. In dementia, and still more in *amentia*, or *idiocy*, recovery is all but hopeless; although by allaying unusual excitement, and occupying the attention with suitable employment, considerable improvement may, in many instances, be effected; and, in particular, the propensity to violence overcome, and the disposition rendered more tractable. In the last report allusion was made to two cases of *moral insanity*, or that form of the disease which is accompanied by perversion of the *moral*, without corresponding derangement of the *intellectual* faculties. Another case has since then come under our notice, in which the means found useful in other cases of insanity effected a recovery, viz.—removal from the scenes

and persons that tended to keep up excited feelings, together with the exercise of moral discipline, and appropriate medical treatment. Such cases are interesting in certain circumstances, from their medico-legal bearing on responsibility.

*Causes inducing the disease in the cases admitted.*

We have endeavoured to exhibit in the next table (No. 5) a connected view of the causes which induced the disease in those admitted within the year; although it must be allowed that every such attempt is necessarily imperfect, from the difficulty of acquiring full information in regard to the history of each case; and of selecting, from several concurring causes, that one to which the greatest influence should be assigned.

TABLE V.

	Males.	Fem.	Total.
Hereditary predisposition.—Exciting cause various, . . . . .	6	4	10
Former attack. — Exciting cause various, . . . . .	4	4	8
Highly scrofulous constitution.—Do. Do. . . . .	2	2	4
Child-birth, and other sources of uterine irritation, . . . . .	0	7	7
Overstrained mental application, . . . . .	1	0	1
Perverted and overstrained devotion, . . . . .	1	2	3
Poverty, grief, and causes of domestic disquietude, . . . . .	1	4	5
Previous disease of the brain, from apoplexy, typhus, &c. . . . .	3	2	5
Intemperance in the use of ardent spirits, . . . . .	4	1	5
Unknown, . . . . .	3	2	5
	25	28	53

It will be observed in how large a proportion the disease was *constitutional*; and that while some of the causes were of a *physical*, others were of a *moral* character,—both being often combined in the same person, and conducing to the same end. Bodily disorder, as indicated by furred tongue, headache, or giddiness, disorder of the stomach and bowels, whether as cause or effect, was a very constant, if not inviolable attendant on the mental disorder. We cannot, however, assert that any of these physical symptoms were in any way peculiar to, or diagnostic of, the malady in question.

Where the general health is thus impaired, grief, and such like moral causes, which, in a state of health, would be suc-

cessfully struggled with, prey on the mind with a power that cannot be resisted. There is reason to believe that the threatened attack of insanity might often, in such cases, be wholly prevented, were the attention of the family physician directed in time to the removal of what at first seems to be only a trifling bodily ailment.

Intemperance in the use of ardent spirits was found to be the exciting cause in five of the cases. In the first stage of insanity cordials are frequently had recourse to, in the vain hope of removing unwonted despondency, while they but too often precipitate the attack. Overstrained mental application, among men, especially when accompanied by *anxiety*, and overstrained and perverted devotion, in females, are not unfrequent causes of insanity. But, amongst the latter class, perhaps the most frequent of all causes are uterine irritations and derangements. Fortunately, the primary disorder is often amenable to medical treatment, in which case the secondary affection of the brain usually subsides; unless, from neglect, that which was functional has assumed the character of organic disease. In a few instances, the insanity was an effect of a previously diseased state of the nervous system, which had manifested itself in the way of apoplexy or palsy. The mental disorder in these cases almost invariably put on the form of dementia, or fatuity, from the first; and the patients generally betrayed a propensity to violence. It is chiefly on this latter account that, although incurable, we are obliged to admit such patients into the asylum.

*Mortality during the year.*

Fourteen patients died during the last year. Five died of *general palsy*; and it may be noticed that these were all male patients;—thus confirming what has been remarked so often in former reports, and what corresponds also with the experience of other institutions, viz., that such palsy is relatively more common in men. Three died of consumption—a disease frequently met with among the inmates of an asylum. Two females, of weak constitution, sank under the exhaustion consequent on a violent and prolonged stage of excitement. Two died apoplectic. One died of dropsy; and one of inflammation of the lungs. In all, with one exception, (where the consent of the friends could not be obtained) an examination of the body was made after death. The morbid appearances corresponded in most respects with those noticed in former reports, and tended to confirm us in the opinion that insanity is not necessarily or essentially of an inflammatory nature in its early stage, though it rarely fails to lead to inflammation; and

its products, when it has continued long. Sometimes the most violent maniacal excitement appears in connexion with a condition of the nervous and vascular systems, in which the patient is calmed, rather than excited, by the cautious exhibition of stimulants; and which leaves, after death, no morbid appearances corresponding to the violence of the symptoms during life.

Opacity of the arachnoid, and a copious effusion of serum, sometimes milky—presenting the aspect of a gelatinous layer over the surface of the brain—were the most common of the morbid appearances; and never failed to be well marked in those who, during life, had exhibited paralytic symptoms. As regards the other organs of the body, disease of the heart, generally in the form of hypertrophy of the left ventricle, was frequently found. Such a condition of the organ must, no doubt, in some instances, have operated as a remote cause of insanity, by exciting, and otherwise interfering with, the regular distribution of the blood within the head; while, in other cases, the strong emotions of the mind, and violent muscular exertions—the result of an excited state of the brain—may have reacted on the heart, and the disease of the latter been in this way an effect, rather than a cause of the insanity. In one of the patients, whose delusions, during life, were of a hypochondriacal nature, the morbid appearances were instructive; for, while the traces of morbid action within the head were slight, an unusual arrangement of the viscera of the abdomen was found, the transverse arch of the colon being tied down to the rectum by a morbid adhesion, so as at all times to have interfered with the functions of the intestinal canal. The symptoms, during life, also indicated some abdominal lesion.

The following table exhibits the principal morbid appearances met with in the brain of those who died during the last year. The disease which was the *more immediate* cause of death is also noticed, and the *form* of insanity during life:—

We would next make a few remarks on the treatment of the patients.

In prosecuting this all-important department, we have kept in view these leading objects—the calming of the excited feelings of the patient, by a gentle and steady system of moral discipline, and the correction of physical disturbance in the general system, and in the brain in particular, with diversion of the mind from the train of morbid thought, by the substitution of a variety of rational and amusing occupations.

The active employment afforded by the possession of the grounds of Clerkseat,

continues to answer our most sanguine expectations. We are surprised to find, from time to time, patients, before doomed to idleness, become active and useful; and in recent cases, the good effects are still more conspicuous in forwarding recovery, and improving the general bodily health. No more cheerful sight can be presented, than a number, varying from twenty to thirty, as happens every day when the weather admits of it, employed in the grounds, each in a manner suitable to his former habits, or bodily strength; the farm-servant at the spade; the gardener, as he was wont, sowing or planting; and the man of better circumstances, hoeing, raking, &c. Employment in the fields is, perhaps, the only one in which patients of all ranks can equally join, being the natural occupation of the poor, and no degradation to the rich. To ensure, however, the successful working of a system so superior to that which condemned the inmates of an asylum to a cell, or a little less narrow space in the form of an airing ground, the most constant superintendence is necessary. To allow a patient, under violent excitement, to have possession of instruments so dangerous as the tools used in agriculture, would be injustice to himself and his attendant. The active stage of excitement is, therefore, allowed to pass by, and every one is encouraged in habits of steady occupation by the *example* of others similarly engaged. The principle is always kept in view, that the ground was procured for the advantage of the patients, and we never allow what was intended for healthy exercise to become a task, believing that the truest profit to the institution and to society, is not the amount of labour accomplished, but the progress that has been made in forwarding the recovery of the patient.

When the out-of-door occupation is over for the day, or the season of the year does not admit of its being carried on, periodicals, and books of an instructive and amusing nature, are put into their hands, and are perused even by persons whose former habits would not, in other circumstances, have led to such an exercise of the mind. Instructive reading, perhaps, more than any other of the moral means of treatment, tends to divert the attention of the patient from the subjects of his hallucinations; and we would, therefore, recommend a continuance of the liberal supply of books hitherto granted.

The female patients are afforded constant occupation, in which former habits and circumstances of life are also held in view. Needle-work, knitting, washing, and laundry-work, can be afforded at all times; and, by way of an agreeable diver-

TABLE VI.

No.	Sex.	Form of Insanity.	Disease which was the immediate occasion of Death.	Morbid Appearances within the Head.
1	Male.	Monomania, with excitement.	Pulmonary consumption.	Effusion of serum under arachnoid; slight congestion of blood-vessels of the brain.
2	Female.	Monomania, with depression, latterly fatuity.	Exhaustion.	Effusion of serum under arachnoid.
3	Female.	Active mania.	Apoplexy.	Great vascularity of the brain, and an effusion of serum under arachnoid, and into the ventricles.
4	Female.	Monomania, with suicidal propensity.	Pulmonary consumption, with ulceration of bowels.	No obvious morbid appearances within the head.
5	Female.	Active mania.	Exhaustion.	Minute and extensive injection of the pia-mater, and numerous bloody points in the white substance.
6	Female.	Monomania, with excitement, latterly fatuity.	Pulmonary consumption.	Remarkably pale and bloodless state of the brain.
7	Male.	Monomania, ending in fatuity.	Paralysis.	Opacity, and effusion of turbid serum beneath the arachnoid.
8	Female.	Hypochondriacal monomania.	Apoplexy.	Considerable effusion of serum under the arachnoid.
9	Male.	Mania, ending in fatuity.	Paralysis.	Appearances exactly similar to No. 7.
10	Female.	Monomania, with excitement, ending in fatuity.	Cancer uteri, with dropsy.	Nearly the same as in No. 6.
11	Male.	Mania, ending in fatuity.	Pneumonia.	Opacity of arachnoid, and atrophy of convolutions of the brain.
12	Male.	Monomania, with excitement.	Paralysis.	Great effusion of serum under the arachnoid, and into the ventricles.
13	Male.	Fatuity.	Paralysis.	No examination.
14	Male.	Dementia.	Paralysis.	Great effusion of serum under the arachnoid, and in the ventricles; softening of the <i>septum lucidum</i> and <i>fornix</i> ; and vascularity of <i>medulla oblongata</i> and <i>tuber annulata</i> .

sion, light gardening, a promenade in the fields, music and reading, present themselves. To those who are aware how the fatuous, and incurable as regards their state of mind, accumulate in an institution unprovided with any subsidiary establishment to which such patients might be removed, it will be sufficient, in order to show to what extent the female patients are employed, to mention, that out of a number varying from sixty to seventy, frequently only three are unemployed.

It remains that we should explain the arrangements to be adopted in the enlarged establishment. The present hall for gentlemen will be occupied by the same class as

before, for which its adjoining colonnade, and excellent airing ground, well adapt it.

The present back-hall is well adapted for an intermediate class of patients, between the former and paupers, and particularly for those who require more than the usual amount of vigilance on the part of the attendants. In improving the airing ground attached to it, a delightful employment will be afforded to the patients.

The hall and work-room of the new buildings, from their size, and vicinity to each other, are adapted for the lowest class, always the most numerous in our establishment.

A similar arrangement will be adopted

in the female department of the house; but the work-room there, will, in the meantime, be used as a chapel, leaving our present chapel as a sick ward.

The range of bed-rooms in the ground-floor of the new buildings are well suited for patients who are noisy during the night; and, in point of appearance and comfort, are an immense improvement on the range of apartments formerly in use for such patients. These, with the bed-rooms in the transverse portion of the new buildings, (also constructed on an excellent plan,) will add forty sleeping apartments to the former accommodation.

In conclusion, it is important to remark that, as regards all the arrangements of an asylum, including the means of employing and amusing the inmates, it should now be held as a principle, that the public wish should be anticipated, and every endeavour used to divest such an institution of whatever tends to suggest the idea of a gloomy or prison-like abode. And a great step, we think, has been made towards this in our newly constructed buildings.

## DIPLOMA OF THE ROYAL COLLEGE OF PHYSICIANS.

THE Censors' Board thinking it desirable that medical students who may hereafter intend to offer themselves as candidates for the diploma of the Royal College of Physicians, London, should be made acquainted with the nature and extent of the examinations they will have to undergo, transmit to the Editor of the Medical Gazette the accompanying papers for publication. It may be necessary to add that six hours are allowed to the candidates, on separate days, to reply to each of the papers. The answers are made in writing, and in English. The candidates are afterwards subjected to a *vivâ voce* examination in each part, this latter being conducted in Latin or English, at the discretion of the Censors.

### FIRST EXAMINATION. IN PARTE PHYSIOLOGICA.

September 1839.

1. WHAT are the muscles subservient to inspiration? and what to expiration?

2. Name the arteries which compose the circle of Willis, and state their origin, and previous course.

3. Describe the origin, course, and termination of the vas deferens.

4. What are the principal conclusions arrived at by Mr. Kiernan, relatively to the structure and functions of the liver? What are the functions of the hepatic artery; of the hepatic vein; of the portal vein, and of the capsule of Glisson, according to that anatomist?

5. State the characteristics of serous and mucous membranes, and mention the point at which a serous and a mucous membrane freely and directly communicate.

6. State the position of the kidneys, and describe their structure.

7. What is the composition of urine?

8. Describe the anatomy of the medulla oblongata, and its connection with the cerebrum and cerebellum.

9. State the origin, the distribution, and the functions of the nerves, which supply the tongue.

*Translate into English.*

Remedia externa si quis quærat ad leniendum Podagræ dolorem accommoda, nulla mihi haecenus cognita sunt (licet plurima tum in me ipso, tum in aliis expertus fuerim) præter merè Refrigerentia et Repellentia, quorum usum jam supra docui periculo haud vacare. Et fidenter assero, multâ et longâ observatione suffultus, maximam partem eorum qui Podagrâ periisse putantur, non tam ipso morbo quàm sublestâ atque indebitâ medicatione fuisse peremptos. Si quis autem Remediorum externorum, quæ pro Anodynâ indubitatis habentur, virtutem probare velit, non fucum sibi faciat eadem sub declinatione paroxysmi particularis (quo tempore dolor jam sponte suâ cessaruset) applicando: quin potius sub initio paroxysmi ista usurpet: et statim edocebitur quàm si culneum sit illud auxilium, quàm vana spes; cum hæc Epithemata nocere quandoque possint: prodesse nunquam. Quâ de causâ egomet jam à multis annis nulla remedia externa adhibui. Pulticula ex pane simaligineo eum Croco in lacte cocto, addito postea Oleo Rosaceo in paucâ quantitate, mihi olim præ cæteris profuit, quæ tamen in paroxysmi initio nihil prorsus juvabat. Si igitur dolor admodum sæviat, æger rectius sibi consulat se in lecto continendo donec is aliquantisper remiserit, quàm Anodynâ utatur: attamen haud abs re fuerit Laudani pauxillum vesperi sumere, si dolor patientiam multum vincat, aliter melius omittetur.—SYDENHAM, *Tractat. de Podagrâ.*

## SECOND EXAMINATION.

## IN PARTE PATHOLOGICA.

September 1839.

1. What are the different forms of malignant disease?

2. What organs are most subject to the different forms respectively, and which of those organs are most frequently affected simultaneously, or in succession?

3. What are the constitutional symptoms attendant upon malignant disease?

4. State what are the chief forms and varieties of *Dropsy*, and on what functional or organic derangements they respectively depend; describing the character of the morbid changes in the various organs.

5. When *Hæmorrhage* takes place by the mouth, state, first, what are the different causes of such hæmorrhage, and secondly, how we can discover the source from which it comes.

6. Enumerate the different deposits which separate from the urine spontaneously in disease.

7. State by what signs, either physical or chemical, these various deposits are distinguished, and what indications they afford as to the seat and nature of disease.

8. In what states of the body, and from what causes, does *Paralysis* occur suddenly, and in what states of body, or from what causes, does it take place gradually?

9. Describe both forms of paralysis in their approach and progress, and state the prognosis in each.

10. What are the causes of *Dysentery*?

11. Describe the symptoms of dysentery, both acute and chronic.

*Translate into English.*

Dolores, qui menstruis instantibus, vel fluentibus oriuntur, tuto leniantur opio. Itaque mulieres, quæ illis opportunæ sunt, debeat semper in promptu habere semigranum vel granum opii, sumendum protinus ut dolor ingruat et, si opus fuerit, semel aut bis, interposita semihorâ, repetendum. Neque opium, hoc modo datum, purgationem istam cohibuit, aut omnino perturbavit. Quodsi a stomacho ægre fertur, commode infunditur in alvum. Quinetiam tinctura opii ventri illita vi anodyna non fuit destituta. Lavatio tepida et vapor aquæ calidæ naturalibus exceptus per paucos dies ante menstrua.

## EPILEPSY FROM TAPE-WORM.

Mademoiselle O., aged 27, and of a strong constitution, had enjoyed good health up to September 1838. On the 19th, after taking a hearty supper, she went to bed, and slept soundly. About 11 o'clock, her father found her without consciousness, with her mouth drawn to one side, and frothy, and making efforts to vomit. Her eyes were haggard, and dulness was the general expression of the features; the complexion was of a deep red. As the absence of paralysis made it probable that it was a first attack of epilepsy, with congestion of the brain, the only measures adopted were the application of sinapisms to different parts of the lower extremities, the encouragement of the vomiting, and the exhibition of an antispasmodic potion and a clyster containing assafetida. The intellect was extremely dull during the night; but in the morning Mademoiselle O. was very well.

The patient having stated that for the last four years she had very often voided small worms, which, according to her description, seemed to be oxyuri, injections were prescribed of salt water into the rectum, and some ounces of castor oil were taken by the mouth. On the 28th of February, 1839, the patient had a similar attack, but more severe.

The next day, at 10 in the evening, there was a fresh fit, which ceased for a short time, but reappeared at 2 A.M. The convulsions were stronger than ever; and the cerebral congestion imitated apoplexy, so loud and heavy was the breathing. The prescriptions were the same as before, and the patient was restored to her usual state. Mademoiselle O. having preserved some of the worms she discharged, they were found to be fragments of tænia; and two ounces of the bark of the root of the wild pomegranate-tree were prescribed, to be boiled in a pound and a half of water down to two-thirds, and to be taken at thrice. The first glassful made the patient feel the action of the medicine by sharp colic, which produced a stool attended by the expulsion of a tape-worm twelve feet and a half long, the neck and head coming away. The other doses did not expel any fragment of the worm; but the next day but one, eighteen grains of calomel brought away two enormous lumbrici. Since that time there have been no more fits.

Epilepsy, or the diseases which resemble it, is as yet but little understood; it depends on so many different affections, and these often very obscure, and it so seldom affords positive indications, that one cannot be too ready to point out the cases where the cause of the symptoms is evident, although we do not know its mode of action. Had these fits been supposed to depend on organic disease, bleedings, leeches, blisters, and moxas, would have weakened the patient, the fits would have become more frequent or more severe, and the result must have been disastrous.—*Bulletin Méd. du Midi*, and *Gaz. Méd.*

## PHYSICAL SOCIETY, GUY'S HOSPITAL.

This Society will resume its sittings on the 5th of October next, when an introductory discourse will be delivered by the Chairman, Mr. Callaway, and a communication read by Dr. Bright.

Of Oxford, &c.

*As delivered at the Royal College of Physicians,  
May 15, 17, 22.*

### ON THE DIAGNOSIS OF DISEASE OF THE HEART.

*Bronchitis.*—Species and diagnostic value of abnormal cardiac sounds.—Principal signs of valvular disease.—Normal valvular sound masked by abnormal sound; case.—Relation of abnormal sounds to the systole and diastole.—Diagnosis of the particular valve diseased.—Author's view of the value of those signs.—Diffusion of abnormal cardiac sounds.—Difficulties from wide diffusion of cardiac sounds.—Difficulties from uncertain direction, &c. of cardiac sounds.—Friction sounds.—Diagnosis by complications.

4. *Bronchitis.*—Of all the concomitants and complications of morbus cordis, the most common by much, according to my observation, as numerically stated last year, is a congested and catarrhal condition of the bronchus, often extending throughout all its lobular ramifications. This complication much exceeds emphysema pulmonum and valvular disease, which I find to be the next most common concomitants, in the pectoral viscera, of cardiac muscular hypertrophy, and is, though more under control of medicine, and therefore less formidable than the latter complications, still an ingredient that adds much bitterness to the sufferings of the cardiac, in more than one way. It is, likewise, on account of its comparative frequency, one of those that most circumscribe the utility of the acoustic semeiology in cardiac diagnosis. On this point, observations laid before the College in the

Croonian series for 1838 offer sufficient illustration. Suffice it now to remind my hearers, that well developed morbus cordis is rarely free from a condition of the air passages that is necessarily productive of abnormal respiratory sounds, and that the act of inspiration in particular is most frequently accompanied by catarrhal murmurs of one kind or other. If the mucous excretions be scanty, and the cough consequently be dry, or without much expectoration, we usually find murmurs of the hissing, crackling, and wheezing, or of the hoarse and snoring kinds; and if the cough be moist, and the expectoration be abundant, we have, on the contrary, some of the various humid murmurs—viz. coarse crepitation, bubbling, gurgling, &c. It is by no means rare to find the expiration accompanied by murmur as well as the inspiration, though usually less loud and prolonged. Now it is plain enough that the coincidence of inspiratory and expiratory murmurs, with obscure because feeble cardiac action, must impede very much diagnosis by the ear, to all but those whom constant use has familiarised with such difficulties. And if to the preceding we add, that in a large proportion of matured cardiac cases, an emphysematous state of the pulmonary structure exists, we shall perceive that in many instances the often useful artifice of suspending respiration will not much avail us, especially where no valvular disease exists, so as to render the character of the sounds a competent test of the heart's condition.

There can be no question, then, that the bronchitis that so commonly accompanies matured morbus cordis, is a source of much difficulty to the diagnostician; so much so, indeed, that when, in addition to a pulmonary catarrh, including the left lung, and producing breathing sounds of the whistling, or snoring, or bubbling character, and not confined to the time of

inspiration only, but extending, as I have often found them, to the expiration also; and when the præcordial portion of the pulmonary lobes is emphysematous, which likewise often happens; and when, likewise, in addition to the preceding, the action of the heart is feeble or sluggish; under such difficulties, so combined—and they must not rarely be encountered in such combination, especially amongst the necessitous classes—I have found the physical exploration generally of very uncertain value, and the auscultation of the cardiac sounds particularly, nearly quite useless.

*Species and diagnostic value of abnormal cardiac sounds.*—I have above noticed the principal modifications of, and circumstances connected with, the sounds of the heart, as elements in cardiac diagnosis, confining my observation to the normal valvular condition, and excluding, therefore, from consideration all varieties of a true or intrinsic character, as well as of diffusion and other extrinsic circumstances, that were not within the range of action of the unaltered valves. I have now to treat of the various modifications of cardiac sound arising out of morbid changes in the valvular tissue, otherwise of valvular disease. From my anatomical investigations already so often referred to, it appears to follow that what has been often designated simply “valvular disease,” has in reality not been valvular disease only, but in truth a combination of muscular hypertrophy, with disease of a valve or valves. Though, therefore, the importance of pure valvular defect or disease, if moderate in extent, and unaccompanied by important muscular disease, or by disease of the great thoracic blood-vessels, might, I conceive, be rated rather low, as compared with the tremendous interest actually belonging to it, amid its usual complications, yet I acknowledge that little blame can attach to the practical man, who has hitherto been accustomed to regard the valvular form of disease of the heart as the great and paramount species of *morbus cordis*; for I fully subscribe to the general opinion, that there is no other form of heart disease of equal urgency of symptoms, or difficulty of alleviation. But to this rule I would, *obiter*, point out as exceptions those pretty numerous cases of *morbus cordis simplex*, or simple muscular hypertrophy, which are distinguished by a peculiar susceptibility in the heart, of violent nocturnal palpitations, and otherwise irregular action; and which may possibly owe some portion of their distressful nature to their including, along with cardiac disease, some peculiar susceptibility in the lungs that constitutes a predisposition to the spasmodic asthma of the older pathologists. And

there is further this circumstance to account for and excuse the pathologist-practitioner's exaggeration of the relative importance of cardiac valvular cases, viz. that not only are the valvular forms of heart disease easily and readily recognized, *post-mortem*, without instrumental aid, which pure hypertrophy very often is not, but even during life their recognition requires, if the heart act with any vigour, a mere smattering acquaintance with the mechanical methods of diagnosis, which cannot by any means be said of most cases of purely muscular cardiac disease.

From what has been already said, it is obvious, then, that I conceive great and peculiar importance to attach to the semeiology of valvular disease, as indicative at once of hypertrophy of the parietes, with all its formidable vital morbid conditions,—and defect at the orifices, with their inevitable inconveniences to both lesser and greater circulations.

*Principal signs of valvular disease.*—The principal signs of valvular disease that I have observed, as worthy of distinct description, are the following:—

1. The substitution of an abnormal sound, widely different from the sound of the normal valve, for the healthy sound of the valve.

2. The coincidence of an abnormal sound with the natural sound of a valve.

3. The absence of all valvular sound.

The principal signs of valvular disease, laid down by preceding writers, which I have not been able to satisfy myself about, and whose diagnostic value I question, if not deny, are the following, viz.

1. Excessive asthmatic distress, recurring in paroxysms more or less protracted, and marked by a darker than common coloration of the face, &c.

2. Dropsical effusions.

3. Venous pulsations.

4. Modifications of the pulse corresponding with the nature, extent, and peculiar seat of the valvular lesion. Upon each of these alleged effects and signs of valvular disease, I shall probably hereafter hazard some observations, with a view to justify my scepticism respecting their alleged diagnostic value and practical importance.

*Normal valvular sound masked by abnormal sound.*—My first sign of valvular disease to be noticed, is the substitution, apparent at least, if not real, of a new and abnormal sound for the natural sound. This is an event of no unfrequent occurrence, and I have met with it as arising from the following causes. Ist, as to the systolic sounds. The suppression or masking of the first sound has been effected, 1, by induration of the mitral valve, and contraction with patency of the auri-ventral or interior orifice; 2, by a condition somewhat simi-

lar of the aortic orifice and valve. The former of these valvular degenerations has been indicated by a sound accompanying the systole, and of variable character, from the softness of wheezing or blowing, to the hardness of an almost metallic clangour. The disease at the aortic opening has similar murmurs with that of the auri-ventral; so far at least as I have observed. In the case of each valve the position holds, that the character of its abnormal sounds has a complex causation, depending partly on the mechanical condition of the valves and orifices; partly on the dynamic condition of the ventricle; partly, also, probably on the crisis, mass, &c. of the blood.

If the valve have become rigid, so as without quite stopping the way, to offer considerable obstruction to the retreat of the blood into the auricle, or its advance into the aorta, during the systole, there must, if the heart act with sufficient vigour, and the blood's condition be not peculiar, be produced certain harsh and loud sounds, that would be heard probably over the whole præcordia, and sometimes in still remoter parts of the parietes of the chest. And on the other hand, assuming the like conditions of the valve and blood, but with a different condition of the heart's action, viz. an asthenic condition, a result very different may ensue, viz. instead of a hard harsh sound, a soft blowing sound, or perhaps no distinct systolic murmur at all. And the diastolic sound is subject to like complex influences and apparently capricious variations; for unless the heart propel with some vigour, and the aorties be deep and wide and flexible enough, and the aorta be sufficiently elastic, the second sound disappears altogether, to give place to an abnormal sound, or otherwise, according to circumstances.

The variations that we observe in the cardiac murmurs, under different circumstances of bodily strength and fulness, or weakness and leanness, are often very embarrassing. Examples of this are the blowing and other noises often audible in the præcordia, &c. of girls, and of which nothing more than purely conjectural explanations have, so far as I know, yet been offered. But such are not peculiar to excitable females structurally sound. In protracted cases of morbus cordis, involving valvular mischief, changes of tone and other characters are observed in the abnormal sounds, under a variety of circumstances. Of this class of cases I have had an example very striking and instructive for the last eight or ten months in the infirmary. The following is a sketch of the case.

CASE.—A female under forty years of

age was admitted into the infirmary in September 1838, with anasarca, and bronchitic and epileptic symptoms. I was soon aware of cardiac enlargement, and at a subsequent period found that her urine was albuminous. On the 10th of October, for the first time, a loud noise was noticed all over the cardiac region; viz. a hard and almost metallic clangour accompanying both systole and diastole; the heart's action being vigorous. On the 13th the same was heard, weak at the apex, but loud over the base. On the 16th the noise had become a bellows sound, and was much abated. Soon after this, mercury was employed, and active mercurialization established, and with great temporary relief, to the convulsions especially, which were suspended for some weeks in consequence. Jan. 5th, 1839: A loud clapping systolic sound heard about the apex, less clear over the base of the heart. On that day in the course of the visit several variations in the murmurs were observed. For a short interval the normal sounds only were heard somewhat obscurely; then, again, they became loud and clear, and then again often a little obscure—especially the second sound. In perfect repose the abnormal sounds disappeared almost wholly; but were at once developed by the slightest voluntary effort. Nothing was audible during perfect repose but a soft blowing sound accompanying the second sound. On the 30th the bellows sound again was so loud as wholly to supersede the second sound. Up to the end of April, the variations from soft blowing to hard bellows sound continued, the blowing sound being the predominant one in frequency of occurrence to my observation. On the 25th April, a hoarse, scraping, or rubbing like sound superseded wholly the second sound, the systole being then free from murmur. To-day, May 8, the sound is soft and blowing, and accompanies the diastole only. During the greater part of her treatment, the action of the heart has been sthenic, but temporary variations were observed in consequence of recent convulsions, or of cupping, which was necessary very frequently, to relieve head-ache, and check the epileptic spasms. The case is quite hopeless, involving, as it does, organic disease in the brain, which is probably the seat of the tumor or abscess in the occipital region, and organic disease of the heart, involving valvular defect, and was obviously on admission a hopeless case. But though offering no field for curative means except as palliatives, it has been both interesting and instructive as shewing the variability of the cardiac sounds in a certainly morbid condition of one or more valves, and especially the mitral, and under circumstances

of vascular plethora and cardiac power, favourable apparently very generally to the development of the harshest sounds the physical conditions of the valves would admit of.

This branch, then, of the mechanical semeiology, partakes, like others, and to some extent, of the uncertainty of the functional or rational signs; for though the fixed and material conditions of a morbid valvular sound be present, that sound may be wanting, because the causation of this part of the physical semeiology is complicated, and involves dynamic or vital conditions of the usual variable characters. Owing to this complexity, no doubt, of causation, and the consequent variability of action and physical effect, it must be that so little valuable information can be derived from attention to the *timbre* or *pitch* of the permanent valvular abdominal sounds; which, *à priori*, are not easily conceived to be so unimportant as, according to my experience, they are found to be in diagnostic practice.

*Relation of abnormal sounds to the systole and diastole.*—A feature of the cardiac murmurs, more deserving of notice than the musical character, is their relation in the order of time to the systolic and diastolic efforts.

Excluding from present consideration the friction sounds attending pericarditis, and assuming that the interior valves are functionally competent, it is obvious that an abnormal murmur accompanying the systole must be referred to some defect about the arterial valves, offering opposition to the current hurrying forward into the arteries. On the reverse, if the arterial valves offer no opposition to the ventricular gush, any systolic morbid sound must be referred to defect about the interior valves, admitting of reflux into the auricles: and with respect to the diastolic morbid sounds, it is equally clear that such irregularities must be referred to defective action of the arterial valves; which latter parts, if the sounds be loud or harsh, and constant, at least during ventricular vigorous action, must be held to be seats of grave structural lesion. I say, if the sounds be loud, or harsh, and constant, because I have not yet, either in the human subject or in experiments on animals, met, in a sound state of valvular structure, with any much more than momentary murmur, more decided than a soft blowing sound.

*Diagnosis of the particular valve diseased.*—A point of diagnosis of much difficulty, but, happily for practical purposes, curious rather than usefully important, is the distinction of the particular valve or valves implicated in disease—whether interior or exterior, whether on the right side or the

left. It might, *à priori*, be reasonably enough supposed, that any valvular defect tending more especially to derange the lesser circulation, should be of more serious consequence than any similar morbid condition endangering only the regularity of the systemic circulation, on account of the greater susceptibility fairly attributable to the lungs and brain, from venous congestion, or, indeed, any abnormal state of humoral distribution. And it might likewise, with much likelihood, be conceived, that a defect of the interior valve (let us suppose on the left side) should be more formidable in its effects, and more conspicuous by its functional lesions or signs, than a defect of the aortic valve; for patescence of the mitral would seem to expose the pulmonary circulation *directly* to more or less of the repulsive force of the systole; whereas, in a sound state of the mitral valve, a patescent state of the aortic would probably not be apprehended to be directly or otherwise formidable to the pulmonary functions. In accordance, possibly, with these general probabilities, in some measure, considerable labour has been bestowed upon the investigation of the diagnosis of these several valvular diseases; and not without apparent success. With regard to the distinction between valves on the same side of the septum cordis, it has been held that it is practicable to obtain an accurate diagnosis by attending to the regions of the chest in which the sounds under examination are most conspicuous; and that, for example, sounds denoting disease of the aortic valve are best heard over the base of the heart, and high on the sternum, while such as denote disease of the mitral valve are best heard about the apex cordis. With respect to the opposite sides of the septum cordis, it is conceived that the valvular affections of the right side are best manifested towards the sternum and scrobiculus cordis; and those of the left side towards the opposite boundary of the cardiac region.

*Author's view of the value of those signs.*—With respect, however, to these means of distinguishing the diseased valve or valves, whether on the same side or not, I have no very decided opinion to offer. Having, early in my inquiries, satisfied myself that in grave chronic disease of the heart the favourite seat of the affection, in point of tissue, is the muscle, and in point of cavity is the systemic ventricle; and having, in abundance of instances, found every where the worst symptoms—such as asthma, habitual short breath, dropsy, visceral enlargements, &c. &c.—in attendance upon a state of disease not including any important or evident valvular, or orificial, or endocarditic, or pericarditic morbid

condition whatsoever, I have not been in the habit of noting with sufficient care the observations upon which any opinion respecting the value of those means of diagnosis should be grounded. I would not, at the same time, be understood to aim at undervaluing the attempts of the meritorious pathologists who have laboured in this field, by me neglected; for although for all practical purposes it is, as I imagine, in valvular cases, and at present, nearly indifferent whether we are able to diagnose accurately or not the particular valve or valves affected, still, in the growth and progress of medicine, from its present infancy of conjectural etiology and tentative practice, up to a maturity, possibly in the near future, of scientific principles, founded on true and ample inductions, and of practical rules deduced from adequate and genuine experience, I am sensible a time may come when the power of diagnosing with very minute accuracy in valvular heart disease, may be of great value, and indispensable for fully successful practice.

*Diffusion of abnormal cardiac sounds.*—One reason I must mention for my scepticism as to the value of the means pointed out as diagnostic of the particular valvular diseases; and it is included in my next topic for observation—viz. the diffusion of the heart's abnormal sounds.

I have already, under the head of the physiological varieties of diffusion of cardiac sound, anticipated much that should otherwise be dilated on here; especially the influence of two conditions often met with in cardiac valvular cases—viz. a condensed state of the left lung, or of both lungs, and an abnormal *timbre* or *pitch* of cardiac sounds: the former circumstance tending to enlarge very much the area of diffusion, by means of the superior conductive power of the condensed lung; and the latter having a like tendency, but for a different reason—viz. the intrinsic superior facility of transmission of louder, harsher, and shriller tones.

*Difficulties from wide diffusion of cardiac sound.*—Now, out of these two circumstances of valvular disease, both of which are frequently present, arises much difficulty; for the sounds are heard, proceed whencesoever they may, over all parts of the præcordia, taken in the largest pathological sense, with but little difference of loudness, provided only the heart's action be sufficiently vigorous. This tendency to wide diffusion of cardiac morbid sounds, is, perhaps, the greatest obstacle that often presents itself to the useful application of the results above stated, of the inquiries of several able and deservedly distinguished pathologists, respecting the regions of the chest in which the valvular

diseases producing such abnormal sounds, express themselves most distinctly. Now if there were no other obstacle, this would be sufficient to restrict very much the diagnostician's success.

*Difficulties from uncertain direction, &c. of cardiac sounds.*—But I apprehend that other difficulties, still less easily surmounted, remain. Excluding from consideration humoral differences and mere variations in force of cardiac action, there are probably modifications in the manner of action of the muscular appendages of the valves, and of the circumferences of the orifices, that must affect materially the acoustic results. The normal action of the parts just named is very complicated. In order that the regular valvular play should be accomplished, a great number of minute parts, muscular fibres, and tendinous cords, divided into numerous separate groups, and very variously circum-scribed as to their attachments, lines of action, and other relations, must co-operate in a fixed order, and each with a determined amount of energy. That such numerous and diversely situate agents do ordinarily act together, so as to accomplish their simple but most important purposes, is, of course, a familiar fact; but it is a wonder notwithstanding—a marvellous result of that complicated organic harmony, hard even in fancy to conceive, established by Him to whom nothing is obscure and nothing difficult. In a process, however, so complex, and depending, for its accomplishment, on conditions so minute and variable, irregularity may, it is obvious, readily happen even in the physiological state, and without decidedly transgressing the limits of health. But in the state of cardiac disease, the probabilities of anomaly in the action of the valves increase and multiply, and in proportion apparently as the functional lesions that characterize the morbid state deviate much or little from the normal standard. The natural order and proportions being infringed upon, even in a few instances, the binding power of habit is probably weakened; long associated and mutually dependent actions become more or less severed; and effective co-operation is often obstructed, and occasionally for a time even wholly suspended. Owing to interruption, such as just alluded to, of the regular actions, simultaneous or consecutive, of the columnæ carneæ, and other contractile parts governing the action of the valves and orifices, it must be that abnormal sounds are not unfrequently heard without corresponding defective anatomical conditions—harsh sounds, considered to denote valvular osseous induration, &c., but without such osseous induration; and soft sounds, supposed to im-

ply defective valvular dimensions, without great rigidity of tissue, yet arising probably from mere irregular valvular tension. Now, for a correct diagnosis of the true state of things in such cases, the data must often be wanting; especially the great datum of a knowledge of the degree of constancy, under like dynamic conditions, of those abnormal sounds. Without such knowledge, no ordinary acoustic symptoms almost would of themselves be sufficient evidence of grave valvular lesion.

Assuming the constancy of abnormal sound to be unknown, it is obvious, then, as above stated, that we might have abnormal sounds without abnormal structure, and assuming abnormal structure, it is to be expected that we should occasionally meet with embarrassing variations, not only in the timbre and pitch, but also in the mode of development, and thence in the extent and direction of diffusion of those abnormal sounds; as appears, for example, to have occurred repeated in the case of Hardiman, above summarily stated.

Now under such variations in the mode, direction, and extent of the development and diffusion of the heart's morbid sounds, I am aware of no rule of semeiology sufficient to enable the practitioner to identify the structural lesions with any thing approaching to certainty and precision. Under such circumstances, the utmost that could prudently be diagnosticated, would be, that some valvular defect, in all probability, existed; while, as to the precise nature or seat of the valvular lesion, it would often be folly to hazard a confident opinion.

*Friction sounds.*—One variety of abnormal sound incidental to cardiac disease remains to be noticed cursorily. I allude to the rubbing sound or harsh murmur, accompanied, when well marked, by a sensation of friction, and occurring, probably, in one stage or other of almost every case of pericarditis, in which the distended pericardial vessels relieve themselves by discharges of coagulable lymph, rather than by copious serous effusion. This sound of rough surfaces rubbing against each other is not always easily distinguished from harsh vascular sounds. Indeed, when the sensation of friction is not very distinct, I know no physical sign by which the acute stage of pericarditis can be confidently diagnosticated. In a good many cases I have met with sounds originating in the heart's cavities, which no ear, I am satisfied, could, without the aid of the sense of touch, or perhaps rather without what has been called by a recent ideologist, *the muscular sense*, distinguish from pericarditic murmurs. I may say further, that cases of valvular disease

are occasionally met with, in which at once audible and tangible vibration, resembling rubbing sounds, occur. The occurrence of adhesive pericarditis, therefore, is a source of fallacy incidental to *morbus chronicus cordis*, with respect to which the observer must be on his guard, and one which might readily lead astray the young and confiding auscultator. However, the diagnosis is not very difficult, when to the mechanical signs we add, as supplementary and often corrective data, the rational signs: for in otherwise doubtful cases, we obtain the needful light from the use of the hand and other means—in feeling and tapping, and otherwise examining the state of the præcordial and other regions of the chest; by means of which we ascertain that there is tenderness in the hypochondrium, præcordial pain, uneasiness, labouring action of the heart, &c. or the reverse of all these; that there is fever, general pectoral distress, &c., or the reverse;—and by inquiring into the history of the case, we ascertain, probably, that though the patient had for months or years been subject to occasional palpitation and other cardiac symptoms, yet that the present præcordial pain, tenderness, &c. are of recent origin, and attributable to a certain exposure, or to a rheumatic attack still in progress, or other obvious exciting causes.

*Diagnosis by complications.*—The next head for observation is the complications of *morbus cordis*, so far as the investigation of those can be expected to contribute towards clearing up the diagnosis in doubtful cases. It is plain enough that the complications of a disease, including in that term not only the coincident functional lesions which are commonly called rational signs, but the structural also, which are more frequently termed complications, must, if sufficiently frequent, be of much importance to diagnosis, as collateral evidence of other, and sometimes anterior and grave diseases. And of the two classes of symptoms just alluded to—viz. the merely functional or dynamic, and the structural or organic—the latter class, or what is best known by the name of complications, is, I apprehend, in most cases the more important and instructive of the two; and for this reason, namely, that it indicates mischief of a grave character in more than one important quarter, and warns us that we have not one simple morbid action or single organic disease alone to contend with.

But whatever correctness may be conceded to the observations just hazarded, in their application to grave diseases in general, there can be no doubt that with respect to *morbus cordis*, they are fully warranted. On this point I may, I think,

refer with confidence to my anatomical observations, submitted to my colleagues last year, in proof that for chronic disease of the heart, complication and multiplied complication is the rule, and simplicity the exception, and the rather rare exception; and that, in fact, certain complications which, when present, could be easily identified, are of such frequent occurrence as to be extensively available as signs in the diagnosis of doubtful cases. Of these complications the principal were either, 1. Pulmonic, or 2. Hepatic, or 3. Renal, or 4. Cerebral, or 5. Dropsy in one or more of its numerous forms.

Under each of these heads it will be now my duty to make some observations; and of all complicating diseases of *morbus cordis*, the most important by far, both in frequency and gravity, are the pulmonic, which I shall have to consider in the first place.

---

ON THE  
ESTABLISHMENT OF HOSPITALS.

*From a Lecture delivered by*

J. M. ARNOTT,

Professor of Surgery in King's College.

---

[It was not our intention to have given any portion of the introductory lectures delivered on the opening of the medical schools, but we have been led to make the following portion, from that of Mr. Arnett, an exception, as it contains some curious information in reference to the origin of our hospitals, as well as some good observations on the use to be made of them. The first part of what follows appeared in the *Times*; to which, however, we append the conclusion of the lecture, which was omitted by that paper.]

THE establishment of a new hospital naturally creates a desire to know something of the origin of such institutions in general, and of the circumstances under which, together with their primary design of affording relief to the sick poor, there has become associated the no less desirable object of communicating that information which is applicable to the use and to the benefit of all. We are indebted for the origin of hospitals to the promulgation of that religion which it is one of the main objects of this College to encourage and support. Before the introduction of christianity hospitals were unknown. Among the most policed nations of antiquity, the Greeks and the Romans, it is in vain to seek either in their annals, or in the remains of their once proud cities, for a

trace not only of hospitals such as they now exist, but of any charitable institutions for the reception of the poor, the orphan, or the sick. Neither the religion nor the philosophy of the ancients conduced to the relief of the unfortunate, while their whole system of civil polity tended to blunt those feelings of humanity which are naturally implanted in us all. The system of slavery was of itself sufficient to check every scheme of universal benevolence. Divided into freemen and slaves, the state, almost exclusively occupied with the former, took little or no account of the latter, who yet formed the great mass of the labouring population. Considered in the light of property, and subjected to the absolute will of their possessors, their treatment among the Romans was usually characterized by extreme harshness, although exceptions not unfrequently occurred which were repaid by the utmost devotion and attachment. And as in health they were left without protection, so in sickness they were often exposed to much additional suffering from the absence on their part of all legal claim to relief or support, and from the want of the sense of moral obligation on the part of their owners or of the community to provide it. In the time of the Emperors, and as late as the middle of the third century of the christian era, the rich, who did not choose to take care of their sick slaves at home, or to get rid of them by homicide, used to send them to an island on the Tiber, on which was a temple of Esculapius, and there to abandon them to their fate. This inhuman practice attracted the attention of the Emperor Claudius, and there is still extant the decree which he issued in order to arrest it, and by which it was ordained that all slaves thus abandoned should, in the event of their recovery, cease to belong to their masters, and become free—a sufficient proof that even at that time no public hospitals existed in Rome.

After the introduction of that religion which looks upon all men as equal, and which inculcates charity as a duty, its disciples at an early period contrived a scheme for the assistance of their necessitous brethren; but this did not, until the fourth century, assume the form of institutions for their reception. As the pure and benevolent system of ethics which they taught and practised became more extensively and firmly implanted in the minds of men, these charitable institutions increased in number by the piety and bounty of individuals, especially of the earlier Christian Emperors, and by the earnest and powerful exertions of the clergy; and they gradually assumed the separate distinctions which prevail at the

present day. In Constantinople, under the successors of Constantine, establishments existed for the reception of the sick, the poor, the orphan, the stranger, and the pilgrim. To all of these the term *hospitium* seems to have been applied in a generic sense, while for each was invented a name unknown to the ancient Greeks, from whose language it was derived—*Nosocomium*, *Zenodochium*, &c. The application of the term *hospitium* was evidently taken from the sense in which it was employed by the Romans. As there were then no inns for the accommodation of strangers, when in foreign countries, or at a distance from home, it was usual for travellers of that nation to be received at the houses of certain persons whom they in their turn entertained in Rome. The connexion thus established was considered an intimate one, and was styled *hospitium* ; *jus hospitii*. The former term was also applied to the reception of a stranger, and to the house or apartments in which he was entertained; and the Roman nobility used to erect the latter, called *hospitalia*, on the right and left ends of their houses, with separate entrances. From these our word ‘hospital’ is derived.

That hospitals owe their origin to the doctrines and practices of christianity, is among other proofs clearly indicated by the language of the Emperor Julian, when, in his character of Supreme Pontiff, and in the course of his attempt to restore and to reform the religion of paganism, he addresses his inferior priesthood. Alluding to the means which he believed had mostly contributed to the dissemination of the new creed, he inculcates (observes the historian), in the most persuasive manner, the duties of benevolence and hospitality, exhorts them to recommend their universal practice, and declares his intention of establishing hospitals in every city, where the poor should be received without distinction of country. “Julian (continues Gibbon) beheld with envy the wise and humane regulations of the church, and did not hesitate to avow his intention of depriving the Christians of the applause, as well as the advantages, which they had acquired by the exclusive practice of charity and benevolence.” Yet, there are some who imagine that they can trace the origin of hospitals to an earlier period. They refer to the temples of Esculapius, to the *officinæ* attached to the *Gymnasia* and *Circus Maximus*, and to the distribution of medicines among the troops. With respect to the temples, there is no doubt that patients from all quarters resorted to them, but their abode was in the vicinity of, not in, the temple; and when it is considered that besides the ceremonies to which they were subjected

on the part of the priests, they were likewise recommended to practise frequent ablations, and to abstain from certain articles of diet—that the temples were usually erected in healthy situations, and that the mind was occupied by a succession of agreeable impressions, we shall probably be justified in inferring that the sick were placed in circumstances more similar to those which the invalid enjoys at the spas and watering places of modern times, than they who are inmates of a public hospital. The *officinæ* attached to the *Gymnasia* and *Circus Maximus* were merely a species of surgery, in which the disabled athletes or the wounded gladiators were immediately attended to. And the distribution of medicines, which is known to have taken place in the Macedonian armies, from the historical fact of Alexander having once been exposed to the murmurs of his soldiery in consequence of its omission, corresponded at the utmost to that which occurs at our dispensaries. Among the Roman armies, it does not appear until the second century of our era that there was any special place assigned in the camp for the sick and wounded, and no public *valetudinarium* existed in Rome until long after this period.

With the institution of religious orders, a prominent part of whose duty it was to solicit alms to tend the sick and to succour the afflicted, the number of hospitals increased, and from this source it is ascertained that some of the oldest and largest hospitals in this and other countries of Europe have arisen. St. Bartholomew’s was originally connected with a priory, so likewise was St. Thomas’s, both hospitals being in existence centuries before the time of Henry VIII. La Charité arose in the same way, and the Hôtel Dieu was attached to the adjoining Cathedral of Notre Dame. Now, the very names of these establishments indicate their Christian origin. As the property and the power of the monastic orders diminished the support of many old hospitals and the foundation of new ones ceased, until after the lapse of centuries, when, from the increased wealth of the community, the growth of intelligence, and more especially the universal spread of Christian benevolence and philanthropy, these institutions have sprung up in greater numbers, and are unquestionably supported in a more Catholic spirit than at any former period of history. To our own country, and to its capital, these remarks particularly apply. Look at the hospitals instituted during the last century. There are Guy’s, the Westminster, St. George’s, the London, the Middlesex, the Small Pox, the Fever, the Lock, St. Luke’s, and three or four Lying-in hospitals. Nor will the present century suffer by compari-

son. Many of the hospitals just mentioned have been rebuilt or enlarged, and their benefits thereby extended. New ones have been founded—I might add, floated;—the creation of a hospital on the Thames, capable of containing some hundred sick and injured seamen of all nations, being one of the most remarkable evidences of the prevalence of that admirable disposition of mind to which I have just adverted. That of the hospital with which we are more directly connected is no less so. It indicates moreover the enlightened spirit of the times, seeing that it is distinctly established and supported as well for the purpose of professional instruction as for the relief of the sick.

Originating with the Christian priesthood, often associated with the principal church of the places in which they existed, and very generally constituting a part of some religious house, it was natural that the care and management of all hospitals should primarily devolve on the clergy,—on those through whose aid and presumed powers of intercession with heaven, restoration to health was looked for and expected. Nor is it surprising that this control should have been retained during the dark ages, and even for a considerable time after the general revival of intellectual activity in the 12th century. Besides being induced by their sense of duty to assist the sick, the clergy were also the only class of men who had the ability or the means of making themselves acquainted with the Greek and Latin writers on medicine, and they were therefore probably the best qualified persons of that period for the offices which they undertook to fulfil. But when law and theology had revived,—when medicine began to make pretensions to the character of a science,—when the three professions which had been frequently united in the clerical order gradually separated, then, by degrees, efforts were made to withdraw hospitals from ecclesiastical superintendence; and it was ultimately determined that they should become secular establishments. In England, in consequence of the Reformation, this took place at an earlier period than in France. In his *éloge* of Sabatier, Percy mentions that so recently as the middle of the last century, the monks at the Hôpital de la Charité succeeded in displacing Louis, and even pretended for a time to make the other surgeons mere spectators of the operations which they conceived themselves able to perform. But it was not until a considerable time subsequently to the separation just alluded to, that the influence of hospitals upon the progress of medicine was felt—not until it had been preceded by the more ardent and successful

cultivation of anatomy in the 10th and 17th centuries, and in this country, not until there had been adopted less stringent regulations with respect to the admission of pupils to these charitable institutions.

At the commencement of the last century there were but two hospitals in London for the sick and lame—St. Bartholomew's and St. Thomas's, and the governors of these wholly refused to allow the education of pupils in the one, and would only admit nine at a time in the other. They afterwards relaxed, and in somewhat more than half a century later had so completely changed their views, that they built and attached theatres to the hospitals, for the teaching of anatomy and the lecturing on surgery, which up to this time had been carried on in private establishments only. St. Thomas's had the priority in this respect, the anatomical theatre having been built there in 1768; at Bartholomew's, although Mr. Pott was appointed lecturer on surgery in 1765, an anatomical theatre was not built till 20 years afterwards. These changes, together with the ready access of pupils to the more recently-erected hospitals, had most important effects on the progress of medicine. As an evidence of this, consult the works produced on surgery since the first third of the last century—the memoirs of the French Academy, the writings of Pott, Hunter, Petit, Desault, Sabatier, Abernethy, Home, Boyer, Scarpa, Dupuytren, Cooper, Hey, Delpech, and of many minor and other living surgeons, and it cannot fail of being remarked how much of the statements, of the opinions, and of the practice of the authors, is based upon the observations made in and on the experience furnished by the hospitals to which they were respectively attached.

The influence of hospitals was sooner felt on surgery than on physic—partly from the less speculative nature of the subject—partly from the precise information furnished by anatomy being more immediately applicable, and having been rendered more speedily available to its purposes—and partly from the stimulus given to the cultivation of surgery, by the education of a number of young men, required by the exigencies of a continued state of warfare. Up to a comparatively recent period, physicians were chiefly occupied in devising, explaining, or applying some general and preconceived theory, taking little account of individual cases, except in so far as they might be illustrative of that theory. They formed their views first, and took their facts afterwards. Morgagni, many of whose cases were obtained from the great hospital at Padua, and Dr. Baillie, who was physician to St. George's Hospital, set a different example;

that example followed, the influence upon hospitals upon the progress of physic has been at least as strikingly marked within a recent period as upon that of surgery, and this change has been further aided by the effect of 25 years of peace in restoring the former to its legitimate importance in professional education.

Of the beneficial effects of hospitals on the progress of physic, I shall adduce but two examples. In the year 1816 Laennec was consulted by a young woman labouring under symptoms of disease of the heart, but whose stoutness of person rendered percussion and the application of the hand useless in aid of his inquiries into the nature of the case. On reflection, the first idea of the stethoscope presented itself to his mind, and having tried the effect of a quire of paper rolled into a kind of cylinder, and applied, the one end to the region of the heart, the other to his own ear, he was convinced that he might thus become possessed of an important means of diagnosis, and he forthwith commenced at the Hôpital Necker a series of observations, which formed the materials for his most remarkable work on mediate auscultation and the diseases of the heart and lungs. Years ago, in the deadhouse of Guy's Hospital, Dr. Richard Bright made a drawing of a diseased kidney which presented certain appearances; the drawing was put aside. Some years afterwards, when he took upon himself the duties of the clinical wards in the same hospital, two of the first cases he had to treat were of dropsy, which proved fatal. Upon examination, the same changes were observed in the kidneys, as in that already mentioned. This was the germ of that great pathological discovery which has given to Dr. Bright an European reputation, and of which the whole bearings upon the practice of medicine have not yet been thoroughly made out. Further instances I need not adduce, for the statement may be taken as correct that public hospitals have more than anything else contributed in the present century to the degree of precision which physic has attained, and have given to it more than it ever previously possessed of the character of a science.

From what has been stated it will have been inferred that the value of hospitals as schools of medicine has been for a considerable time felt and acted upon in England. But the best method of rendering available these advantages has only been pursued within a very limited period. In so far as brief remarks, made occasionally and irregularly at the bedside, constitute clinical instruction, this has probably been practised from the first admission of pupils to these institutions. But the system of taking individual cases of disease, and

making them the subject of lecture, was in the first instance adopted in Holland, at Utrecht, and Leyden. Thence it extended to Pavia, Vienna, and Edinburgh, and was for a long time confined to these schools, and applied to physic only. Desault, in the Hôtel Dieu, first employed the method systematically in the teaching of surgery. In this metropolis it was, I believe, first introduced by Sir Charles Bell. In physic I do not know by whom it was primarily adopted, but it was practised by Drs. Fordyce and Wells at St. Thomas's Hospital. The regular application, however, of clinical teaching in both departments of medicine, as an essential part of education, is but of yesterday. Its advantages, and the method in which it is proposed to employ it at King's College Hospital, merit notice; but, before advertising to these, it is my duty to recollect that some of the gentlemen I address are only beginning their professional education; and that those who are in this situation, coming to a study at once novel and difficult, and of the nature of which they may probably have formed but a vague notion, are apt to be embarrassed by the number of lectures they find commencing at once, and by the diversity of subjects, all apparently of equal importance, to which they must now direct their attention. It is, I conceive, one of the objects of an introductory lecture to endeavour to dispel this feeling of perplexity, by concisely bringing before the mind of the pupil the purpose and nature of all these studies—by indicating their relations to each other, and comparative importance—and by pointing out the methods by which they are best to be cultivated.

[The learned professor then proceeded to call the attention of the gentlemen assembled to the great purposes of medical education, and the ample means which King's College afforded for the effectual pursuit of objects so important to themselves and to the community at large. With great clearness and precision he presented to his audience practical views of that course of education on which many of them were about to enter, and in which some had already made considerable progress. After dwelling upon the value of a sound preliminary education, and on the absolute necessity of a thorough acquaintance with *materia medica*, anatomy, and physiology, with a competent knowledge of natural philosophy, comparative anatomy, chemistry, and botany, and after much valuable advice as to the most advantageous modes of pursuing the study of those sciences, he went on to say—]

Such are the branches of medical science taught in this college—such are the means

possessed, and the methods employed, to impart it. By giving up yourselves fairly to the purpose, and by availing yourselves of the facilities which your position here offers, you may and ought to acquire a competent knowledge of medicine as a science. But to learn and become familiar with it as an art—to know how to employ it practically, something different and much more is necessary. Neither one nor all the branches together that we have been considering will teach this. Anatomy will not do so. A man may be a perfect anatomist, and yet unable to recognize the nature of an injury in the living body, or to discriminate one disease of an organ from another. Even the systematic lecturers on medicine, surgery, and midwifery, which bear more immediately on the subject, will not communicate to you this practical faculty. You may have attended the lectures sedulously—read carefully on the subjects treated of in them—be able to pass even an examination thereon with tolerable credit, and yet, when brought to the bedside, not know how to interrogate or examine a patient—be incapable of distinguishing a disease, and incompetent to determine what plan of treatment or what particular remedy is best adapted to the case before you. Systematic lectures on diseases are excellent means of conveying to the mind of the student the general truths or principles of medicine (all that observation and experience up to the present period of time has taught us to believe as true.) They are likewise useful for giving a general outline of the characters of particular affections. But the impressions received of the latter are necessarily imperfect, and sit somewhat loosely on the mind; they want the clearness, precision, and force, which the original alone can give. Those who are acquainted with diseases from description only when they come into contact with the reality do not readily recognize the objects before them, and in their embarrassment are either deprived of all power of decision, in perhaps very urgent circumstances; or, mistaking the case, they display a degree of activity and vigour which may be possibly as injurious as it is uncalled for and missapplied.

It is an imperative condition of the knowledge of our art that it should be learned on the living body; there the great masters of it have acquired their skill, and it is from that source that you must obtain those correct and enduring ideas of disease and of its treatment which are subsequently to guide you in endeavouring to emulate them. It is a disadvantage attending the acquisition of this great division of our subject that we cannot always command the opportunity of presenting for your observation the ob-

jects which we might at a particular time seek to make you acquainted with, and that we are mainly obliged to depend upon what chance may offer. Fortunately, public hospitals, by bringing together numerous instances of injury and disease, obviate much of this difficulty, by affording us a greater number and variety of examples in a given time for observation and comparison. There, also, patients are placed in circumstances and under a degree of control much more favourable than elsewhere for witnessing the course and termination of disease, for ascertaining the effects of remedies, and for investigating, in cases of fatal result, the appearances met with after death. No other institutions afford equal opportunities for acquiring a familiarity with operative surgery—not only the operations themselves, but the treatment of the cases before and afterwards. Whatever manual dexterity repeated performances of operations on the dead body may give, none of the difficulties and anxieties are felt which attend those on the living, where alone they can be truly estimated. The advantages of hospitals for the purposes of practical instruction are so justly appreciated, that it would be superfluous on my part to allude to them. We have still, however, to consider the manner in which these can be rendered most available. By merely following in his daily visits a physician or a surgeon (who is under no obligation to be communicative), you would learn something by observing how he fulfilled his duty to the sick, but that only after the expenditure of a great deal of time and labour. Now in the limited period which you can devote to your professional studies, it is most desirable that you should economize both; and it is one of the great objects of the plan of teaching called “Clinical,” to effect this by facilitating the inquiries of the pupil in every way, and, above all, by teaching him how to observe, and what to observe. It will be the duty of the clinical teacher, in every case which comes before him, to point out the symptoms by which the existence of disease is to be recognised; to mark those by which the particular form of disease is to be distinguished from others which may resemble it; to indicate the circumstances on which our opinion of its degree or severity is to be founded; to state the reasons why a certain plan of treatment is adopted, and why a particular diet, particular remedies, applications, or operations, are resorted to; and, lastly, in the event of death, to describe and explain the appearances and changes observed, with their bearings, either as illustrative of the nature of disease, or of the effect of treatment. Much of the duty

of the clinical teacher may be done at the bedside, as much as may be consistent with the comfort and welfare of the patient, but a great deal can only be done, and properly done, elsewhere—in the lecture room, where we can speak more freely and fully—where, also, we can compare cases together, notice omissions or errors, if such have occurred, and discuss unsuccessful cases, from which, very frequently, both in medicine and in surgery, much instruction may be derived. In King's College Hospital both these methods will be pursued. It is intended that each of the medical officers shall in turn take upon himself for a period the duties of clinical lecturer, and during that time he will have under his care, in wards allotted for the purpose, such cases as he may select. But the other patients in the hospital will contribute to the purposes of instruction, by the bedside remarks of the attending physician or surgeon. And the same end will be kept in view in the attendance on and treatment of the out-patients.

Although the advantages of hospital practice and of clinical instruction are now fully conceded, an opinion prevails with some persons in reference to them, which, if acted upon too rigidly, tends to prevent pupils from availing themselves of these advantages during the earlier part of their studies. It is said that to derive the utmost possible benefit from them, it is necessary to possess previously a considerable amount of theoretical knowledge, and hence the expediency of deferring hospital practice until the latter part of the whole course of study. It is undoubtedly true that attendance in the wards is not so profitable to those commencing their professional education as to those who are advanced in it; but it does not, therefore, follow that the time for allowing the former to witness the actual symptoms and treatment of disease should be so long deferred. The advantages of personal observation are so great, that the student can scarcely too soon combine the reality with the description. Certainly, he may begin to do this when he has acquired some knowledge of anatomy and physiology. No doubt, at first, a great deal will be very obscure; he will not be able to account for much that he sees; he will not be able to comprehend the importance of certain symptoms, the interest of certain facts which arrest the attention of his senior fellow-pupils: Let him, however, not be discouraged, or cease from observing the facts carefully; it will frequently happen that, at a later period, when he is further advanced, they will recur to his mind, and he will then be able to analyse the various circumstances connected with them—to refer the symptoms to the cause

which produced them. Further, the early association of practical observation with scientific instruction, besides leading the pupil to apply the notions he has already acquired of the form, the structure, and the uses of parts, to the recognition and explanation of disease, serves as an inducement and an encouragement to him in the pursuit of his other studies. Witnessing the application of anatomy to the diagnosis, the explanation, and the treatment of disease, he prosecutes that science with an interest and zeal which, without practical examples of its utility, is not so effectually maintained. Even in respect to those lectures which are by some considered introductory or preparatory to hospital practice, the systematic lectures on medicine and surgery, a previous acquaintance with disease and injury is most advantageous, for undoubtedly those pupils who possess this derive more benefit from these lectures than those who have it not.

But, in truth, all the parts of medicine are so closely connected with each other, that, begin with what subject you please, the study of this always presupposes a knowledge of others which can only be acquired subsequently. On these various grounds I am of opinion, that the commencement of attendance upon hospital practice should not be delayed beyond the first six months of the pupil's entrance upon his professional studies, that it should be continued during the remaining period of his education, but that the attendance should not be taken into account for his certificate until after he shall have completed his eighteenth year. It is to be regretted, that by those who possess the power of conferring the honours and the privileges of the profession no examination is made which can serve as a test of the knowledge of the pupil in the practical part of his art. Dried bones and preparations, plants, drugs, and minerals, may indeed be presented to the candidate for recognition and description; but no example of disease in the living body will be submitted to him, that the case may be examined, its nature ascertained, and the appropriate treatment laid down by him. It may be, and, no doubt, is right, that the pupil should devote a certain number of years to the study of his profession, that he should attend courses of lectures on certain subjects, and that each of these courses should not consist of less than a certain number of lectures. And, unquestionably, it is necessary that examinations should be made, in order to secure a proper knowledge of the preliminary and collateral branches of study. But that no proceeding should be adopted by which the capabilities, the fitness of the candidate for the actual performance of

the duties of his profession can be ascertained, is an omission as much to be lamented, as the causes of it are evident, and not likely to be removed. The difficulties in the way of obtaining opportunities for making the examinations might be got over, but the cost of time and labour which it would require from those who ought to conduct these, involves a sacrifice no professional man is called upon to make without adequate remuneration, and that adequate remuneration the State is not likely to grant.

In the absence of this most useful stimulus to exertion on the part of the pupil during his hospital attendance, (I mean the knowledge that he will be subjected to a practical examination,) we have thought it right to recommend certain arrangements which may in some degree supply its place, as they will most assuredly shew our sense of the great importance of the object in view.

We propose, in the first place, that the dressers and the clinical clerks, in King's College Hospital, shall be selected from among those pupils who have been most assiduous in their attendance in the wards, and who have given the most satisfactory proofs of their having profited thereby. Of the benefits to be derived from these appointments there is no question, from those who hold them being brought daily into contact with the sick and injured; from their being obliged to keep an account of their cases; from the facility they acquire in prescribing, and from the expertness they gain in the performance of many minor surgical manipulations. It is invariably found that, other circumstances being equal, the dressers derive greater profit from their hospital attendance than the other pupils; and this is still more true of the clinical clerks.

The house-surgeon we propose to elect, by examination, from among the dressers. This office in a public hospital is without exception the most advantageous that a young man can hold for acquiring a thorough knowledge of the practice of surgery. It is not merely the constant opportunities for observation which it gives him, the daily intercourse which it brings him into with the surgeons, but the hourly calls that are made for the exercise of his own judgment and abilities, and for the application of his own acquirements and skill, which give to this appointment its great value. I have never known one who had held the office but who esteemed it as the most fortunate circumstance in his educational life. Those who have had the good fortune to be placed in it generally commence the practice of their profession with a confidence in themselves,

which is rarely felt but by practitioners of some years' standing.

But these appointments can be held by a limited number of pupils only; and although much is expected from the emulation they may excite, yet, to ensure attention from all, a system of interrogation on the cases before them will be applied to the pupils generally, or at least to the more advanced of them.

I have mentioned that accounts of the cases in the hospital, taken by the house-surgeons, clinical clerks, and dressers, under the supervision of the physicians and surgeons, will be kept. These case-books will be open to your inspection, an advantage to the junior pupils more especially, by furnishing them with a full and connected history, which they might not be able to obtain for themselves, and which they might wish deliberately to consider.

But this advantage should not be overrated, and the pupil continue to be satisfied with reading, hearing read, or even copying these cases. This would be neglecting the active exercise of his own powers of observation, investigation, and description, in the situation and circumstances most favourable for cultivating them. He should then, as soon as possible, take notes for himself, and only refer to the hospital books for the purpose of checking and correcting his own.

These, then, are the means by which we expect that King's College Hospital will be rendered as useful to the pupil as we trust that it will prove beneficial to the sick.

If in the course of this address it should seem that I have not dwelt in terms sufficiently commendatory upon the sciences accessory to medicine, I may here be permitted to state, that this has not arisen from ignorance of their importance, or from insensibility to their attractions; and I beg to add, that if your inclinations and circumstances lead you to study profoundly anatomy and physiology, without reference to physic or surgery—if they equally lead you to study chemistry or botany, you have opportunities and advantages here which you may never again possess, and that each of these sciences offers a field for distinction and honours which have not been unfrequently obtained by members of our profession.

In adverting to the want of a practical examination previous to the granting of diplomas, I entirely disclaim imputing blame to any body of men. I have mentioned it as a defect, but as a defect which has a most material influence on the direction of your studies. It is not that I allege or complain that the effect of the present

system of examination is to direct too much of your thoughts to the scientific part of your profession, but that sufficient attention is not thereby ensured to the paramount object of all medical education, the acquisition of practical skill.

I trust, however, that I may have succeeded in impressing you with a conviction of its necessity, and that when the hospital is opened you will bear in mind the opinions I have now expressed, and the recommendations I have ventured to give.

### ON THE SOUNDS OF RESPIRATION AND OF THE VOICE\*.

By PEYTON BLAKISTON, M.D.

Physician to the Magdalen Asylum, and the  
General Dispensary, Birmingham.

(For the *London Medical Gazette*.)

**RESPIRATION.**—On applying the ear to the neck and chest of a person in health, certain sounds are heard during respiration, which vary with the region in which they are listened to.

In the trachea, a coarse hollow sound is heard during inspiration and expiration, (Tracheal respiration.)

At the upper part of the inter-scapular region, the sound during expiration is less intense than that during inspiration, and both are softer and weaker than in the trachea, (Bronchial respiration.)

At the remaining parts of the chest, the sound during expiration is scarcely perceptible, being in most cases reduced to a short puff; while the sound of inspiration is much softer and weaker than at the inter-scapular region (Vesicular respiration.)

This description of vesicular respiration differs from that of Laennec, who remarks, "*en entend pendant l'inspiration et l'expiration un murmure très légère, mais extrêmement distinct, qui indique la pénétration de l'air dans le tissu pulmonaire, et son expulsion*"; thus failing to observe the disproportion between the duration of the sounds of inspiration and expiration. Those persons who are in the daily habit of practising auscultation of the chest, will, however, I think, confirm the accuracy of the description here given.

I shall now endeavour to ascertain the manner in which these sounds are produced, and the causes of the variations

in quality, intensity, and comparative duration, observed at different parts of the apparatus in which they are engendered.

This apparatus consists of a tube commencing at the mouth, divided and subdivided until it terminates in the air cells. During inspiration air is pressed into it by the weight of the atmosphere, and is expelled during expiration by muscular reaction, and by the resilience of the air cells and of the cartilages of the ribs. In thus passing and repassing through these tubes, the air meets with obstacles at every point where their direction is changed. Now when a current of air meets with opposing obstacles, as the wind blowing upon trees, or into a tube inclined at an angle to its direction, it is thrown into sonorous vibration, and therefore noise must be produced in the trachea and its division during respiration. This sound is not sufficiently intense to be heard until the listener places his ear in contact with the trachea; in the same manner as the noise produced by a gentle blowing on a sheet of paper is not heard until the ear be placed on the paper.

The coarse hollow sound, then, heard in the trachea, is produced by the whole air of respiration passing and repassing through this tube, and its upward and downward continuations.

At the upper part of the inter-scapular region many circumstances concur to render the sound weaker and softer than that heard in the trachea. This tube has now been divided into at least two branches, one for each lung, and hence only half of the air which enters the trachea can pass through each division; and therefore the sound generated in either of them by the friction of the air becomes proportionably weaker: and as regards the sounds similarly generated above and below this point, and respectively carried up to it by the current of inspiration and expiration, those produced in the mouth, fauces, and trachea, are weakened by divergence, and those produced in the bronchial tubes are those of one lung only, whereas the sounds generated in both lungs were carried through the trachea. Besides this, the bronchial tubes are not in actual contact with the walls of the chest, even in this spot, but are separated from them by more or less of the spongy tissue of the lungs, which, being a non-homogeneous substance, and consequently a

\* Read before the British Association for the Advancement of Science, Aug. 27, 1839.

very indifferent conductor of sound, deadens and weakens the respiratory sounds in their passage from the tubes to the ear of the auscultator. I stated that the sound during expiration was less intense in this region than that during inspiration. This arises from the additional force given to the latter sound by the vesicular respiration of the intervening portion of lung just mentioned, the sound of which is chiefly confined to the time of inspiration.

When at length the ear is placed on the remaining portions of the chest, it is no longer approximated to the *sides* of the bronchial tubes, but to their vesicular *extremities*. These are so numerous (being not only spread over the periphery of the chest, but also forming the greater part of its internal substance) that only a very minute portion of the air of respiration can reach them at any one spot, and hence very little noise can be produced in them by friction; while the sound generated in the larger tubes, although confined from total divergence in the air, is amazingly weakened and softened by the extent of surface over which it is thus spread. The sounds previously heard at the sides of the bronchial tubes are here effectually prevented from reaching the ear by the great intervening mass of spongy lung. All these causes combining to weaken the respiratory sound, the maximum intensity of which in the trachea can only be heard when the ear is brought into contact with its side, it would not be surprising were no sound detected during respiration at the surface of the chest. Another force, however, is in action. As the wind bears upon it sounds which from their great distance would be otherwise inaudible, so does the current of air during inspiration carry up to the ear those sounds which are engendered in its passage, while that during expiration acts in a contrary direction: hence the sound of inspiration is distinctly heard at the surface of the chest, while that of expiration is barely perceptible.

I shall now endeavour to ascertain where the sound of vesicular respiration is produced. Sound must be generated in every part of the trachea and its divisions during respiration, but it does not follow that every portion of it should be sufficiently intense to reach the ear of the auscultator at the surface of the chest. I cannot deny that a fraction of

that which is heard in vesicular respiration may be produced by the friction of air against the interior of the vesicles, or by that of one vesicle against another, or by that of the pulmonary on the costal pleura, because a slight sound is heard at the commencement of expiration when the force of resistance is at its maximum; but I contend that the *principal* part of it is not thus produced; otherwise, taking place immediately under the ear, and therefore unaffected by the direction of the current of air, it would be heard as distinctly during expiration as inspiration; nor on the other hand can it be principally formed in the mouth and fauces, otherwise it would be much strengthened by stertorous breathing, which is not found to be the case. The sonorous waves formed in these parts, in passing through tubes, the calibre of which rapidly diminishes, and the direction of which is constantly changing, would seem to be in a great measure broken and destroyed before they reach the vesicles. We seem, then, to have arrived, *par la voie d'exclusion*, at the bronchial tubes, as the parts in which the sound heard in vesicular respiration is principally generated; and this conclusion derives some confirmation from the fact that sibilous and sonorous râles, which are undoubtedly formed in these tubes, modify, and in some cases, totally mask the sounds of vesicular respiration.

When in certain diseases a portion of the lung becomes converted into a solid mass, vesicular respiration is replaced over the spot where that portion is in contact with the walls of the thorax, by bronchial respiration, as it has here been defined, coarse, with prolonged expiration. In endeavouring to account for this alteration, Laennec remarks\*, "Les raisons de la respiration bronchique me paraissent assez faciles à donner. En effet, lorsque la compression ou l'engorgement du tissu pulmonaire empêche la pénétration de l'air dans les vésicules, la respiration bronchique est la seule qui ait lieu;" and Andral writes†, "Elle nous paraît dépendre de ce que l'air ne peut pas pénétrer au-delà des gros tuyaux bronchiques." Thus both writers agree in considering the bronchial tubes, which lead to the solidified lung, as the seat of the bronchial respiration.

\* Vol. i. p. 56; 3d Edition. Paris.

† Vol. i. p. 432; 3d Edition. Bruxelles.

tion which is heard in such cases. It must be remembered, however, that the current of air in the bronchial tubes owes its existence to the expansion of their vesicular extremities, and that when their expansibility has been destroyed by the deposition of solid matter in them, that moment the current must cease in these tubes, and with it the sound of respiration within them. Were the larger tubes sufficiently elastic to keep up a current, then, in a solidification of a whole lung, we should hear loud bronchial respiration, which is not found to be the case.

Dr. Jackson, of New York, was the first to notice prolonged expiration as a characteristic sign of bronchial respiration. He writes\*, "In some commencing cases of phthisis, where the respiration is not yet truly bronchial under the clavicle, when we still hear the vesicular expansion and nought else on *inspiration*, I have discovered the bronchial sound on *expiration*. In other words, as the tubercular deposit advances, the bronchial *expiration* may be heard before the bronchial *inspiration*; it may be heard at an earlier period of the disease, and may thus become a very important sign, as making known the disease yet sooner after its origin. This circumstance is very explicable. As soon as tubercular matter is deposited, there exists a solid material around the bronchia, which will transmit the sound made by the passage of the air through these tubes; but thus early a great portion of the lung, even in the part affected (the summit), is permeable to the air, and therefore the murmur of vesicular expansion on *inspiration* entirely masks the sound of the air passing through the bronchia, which would otherwise have been transmitted through the surrounding denser medium. On expiration, however, circumstances have changed: the air, on passing through the bronchia, produces the same sound as on its entrance, and as now there is no vesicular expansion to mask it, it is easily transmitted through the diseased or condensed part to the ear of the observer." Fully acknowledging the practical value of the prolonged sound of expiration as a diagnostic sign, I cannot admit the correctness of Dr. Jackson's observation that it is heard at a period when the sound of inspiration

is purely vesicular. Although it is easier to discover the presence of a sound at a time when none was previously heard, than to detect an alteration in the quality of one previously existing, yet whenever I have perceived the sound of expiration prolonged at the surface of the chest, I have at the same time found the sound of inspiration stronger and coarser than usual; in short, I have found both sounds bronchial. Neither do I think can Dr. Jackson's explanation be considered satisfactory. We cannot understand how the strong coarse sound of bronchial respiration can be masked by the softer and weaker sound of vesicular inspiration, which has in fact been shewn principally to consist of that bronchial respiration modified and weakened by divergence, and borne up to the ear by the current of air. Again, were any portion of lung to be solidified and made sufficiently homogeneous to transmit the sound of expiration, it would also transmit the coarse undiverged sound of inspiration which takes place in the same tubes.

I would submit that when bronchial respiration is heard over a solidified portion of lung, it is caused by the passing and repassing of the air through bronchial tubes leading to *healthy expansible* vesicles, and it is made sensible to the auscultator by his ear being brought into mediate contact with their sides by the solid lung.

VOICE.—I shall next endeavour to discover the causes which tend to modify the sounds of the voice.

According to the researches and experiments of Professor Willis, the voice is formed in the larynx by the vibration of the vocal cords or plates when their planes are in a vertical position, being put into motion by the passage of the air from the lungs. The vocal apparatus, therefore, is a wind-instrument, consisting of a tube with membranous tongues.

It has long been noticed that *timbre*, a quality of tone of wind-instruments, depends much upon the material of which they are made. Wishing to know more upon this subject, I successively placed similarly constructed pipes of wood and of metal on the wind-chest of an organ; and I found that the tone became coarse, and buzzing, in proportion to the elasticity of the material. Having next varied the weight on the bellows, I found the coarseness of tone

\* Life of Dr. Jackson, p. 129.

to increase with the force of the blast. Lastly, by making use of pipes of different degrees of thickness, but of the same material, I found that the coarseness varied inversely with the substance of the pipe. In each of these experiments the coarseness of timbre was proportionate to the degree in which the material of the pipe entered into vibration. Hence, I concluded that *the timbre of wind instruments depends upon the proportion in which the solid vibration of their material are united with those of the air within them, in the formation of the resultant undulations.* Now we can hardly conceive two kinds of undulations thus uniting in different proportions without an effect being produced on the *form* of the resultants to which they give rise; and therefore it is rendered highly probable that each timbre has its corresponding form of wave. Leaving the further consideration of this subject for another time and place, I would merely remark that a jarring must take place between the undulations of the air, and those of the material of the tube surrounding it. For when the instrument is sounded, each section of the column of air, having a tendency to spread in all directions, will produce an outward bulge in the elastic material; in the next moment reaction will take place, and an inward bulge will be produced in the same spot; but by this time (the blast continuing) the next section of air will have been forced on to this spot, and, expanding, will tend to produce an outward bulge in the material, and must meet and receive a jar from the inward bulge just mentioned.

The correctness of the law which I have thus deduced from experiment, is further confirmed by reference to a few facts of daily observation. The upper notes of a flute, formed by small feeble aerial vibrations, are soft and sweet; the bass notes, formed by large powerful waves, which strongly affect the material of the instrument, are coarse and buzzing. The timbre of all reed-instruments partakes more or less of this character, inasmuch as the vibrating reed communicates its motion to the solid instrument to which it is fixed, and causes it to vibrate with some force. Owing to the elasticity of their material, brass instruments give out the greatest possible coarseness of timbre. In the French horn, which is very long, this is not so much marked

as in the trumpet, in which the whole column of air can be suddenly thrown into strong vibration by a quick forcible blast, and can thus be made to act powerfully on its material. A certain degree of thickness is required for a flute, in order that its tone may be sweet and clear. So when any one is desirous of imitating the tone of a brass instrument with his voice, he shapes his lips in such a manner as to make them vibrate strongly; and the moment the nose is closed, a coarse nasal twang is produced by the vibration of the nose itself, which may be felt with the finger, and which is produced by the reverberation of the aerial undulations within its cavity.

To return to the voice.

When the stethoscope is placed on the trachea of a person engaged in speaking, the voice seems to mount up the instrument, as if the speaker's mouth were placed close to the ear of the auscultator, and it has a peculiar buzzing tone, which excites a tingling sensation in his ear, (Pectoriloquy).

On placing the stethoscope at the upper part of the inter-scapular region the voice seems to issue from the spot on which it is placed, and its timbre is still coarse and buzzing, (Bronchophony).

When this instrument is placed on most other parts of the chest, no resonance or unusual quality of the voice is perceived.

It appears to me, that this alteration of the timbre of the voice in pectoriloquy and bronchophony, as compared with that which it has when heard issuing from the mouth, when the ear does not approach the neck or chest, has not been sufficiently noticed. Laennec, it is true, speaking of bronchophony, remarks\*, "Son timbre a quelque chose d'analogue a celui d'un porte-voix;" but the modification which the voice undergoes in passing through a speaking trumpet has very little resemblance to the buzzing timbre of bronchophony in many cases.

In the formation of the voice, as in the notes of wind-instruments, two kinds of undulation are exercised—those of the air which passes through the larynx during expiration, and those which are communicated to the trachea by the vocal plates; and, according to what has been proved in regard to wind-instruments, the timbre of the voice

\* Vol. i. p. 66; 3d Edition.

must depend upon the relative proportion between these two undulations.

When the stethoscope is applied to the trachea, the sounds generated within the latter have to pass through its substance before they can reach the ear of the auscultator, and are therefore conveyed to his ear much more freely through the solid material of the stethoscope, than through the column of air contained in it, inasmuch as all sounds are propagated much more freely through media of similar molecular construction to those in which they are generated, or to which they have, as in this case, been transferred, than through those which are differently constructed. In the sound, therefore, thus conveyed to the ear, the solid bear a greater proportion to the aerial vibrations than in that which reaches it in the ordinary way through the air, when the converse takes place. This accounts for the voice sounding coarser and more buzzing when heard through the stethoscope, than when heard issuing from the mouth of the speaker. Its sound, too, in the former case, is transmitted to the auscultator with an intensity undiminished by the divergence between the mouth of the speaker and the ear of the listener, which takes place in the latter case.

These undulations which enter into the formation of the voice have a tendency to spread, not only in the direction of the mouth, but also towards the periphery of the chest. Their progress in this direction, however, is opposed by the current of air during expiration, and by the increasing mass of spongy non-homogeneous lung. When, therefore, the voice is listened to at the upper part of the inter-scapular region, it is found to resound less than in the trachea, because the aerial vibrations have been opposed by the current of expiration between this point and the larynx, and because the spongy lung has already begun both to surround the air-tubes, to interpose itself between them and the walls of the chest, thus deadening the solid vibrations of the tubes, and more or less interfering with the transmission of sound from them to the ear.

Lastly, at the surface of the chest, between which and the larynx the *whole* current of expiration has opposed the aerial vibrations, and where a very large mass of spongy lung surrounds the air-tubes, and is interposed between

them and the ear, nearly all resonance of the voice ceases.

In certain states of disease, pectoriloquy and bronchophony are heard at parts of the chest where no resonance of the voice is perceived in health; and not only does the resonance vary in different cases, but also the timbre of the voice; in some cases sounding remarkably clear, in others very coarse and buzzing, with every shade between these two extremes. The law of timbre laid down in this paper, will, I think, account for these differences. Thus, when a tuberculous cavity exists near the surface of one of the lungs, and contains but little fluid, the resonance of the voice is strong, and its timbre clear. In this case, owing to the diminished elasticity of the lung which surrounds the cavity, the current of air is lessened, and in some cases stopped, in consequence of which the aerial undulations are propagated freely into the cavity, and are there strengthened by reflection and echo; hence they predominate over the solid vibrations, and soften the timbre of the voice, while they increase its resonance. When a cavity exists, surrounded by much solidified lung, the resonance is still great, and the timbre becomes much coarser, owing to the increased force of the solid vibrations. When the lung is solidified, without containing any cavity, the resonance is usually less than in the former case, but the coarseness of tone is much increased by the same law. Much depends on the proportion between the power of the voice and the extent of solidification. When the voice is very strong it will throw a whole solidified lung into vibration, and give rise to coarse bronchophony, but this is rare. In the case of a female with medullary sarcoma of the upper half of the right lung, there was no resonance of voice, because the main tube of the lung was filled with solid and semifluid matter, so that the vibrations of the voice could not penetrate the bronchial tubes at all. The buzzing quality of the voice was most strongly marked in the case of a man in the wards of Addenbrook's Hospital, Cambridge, whose right lung was studded with lumps of chronic induration, varying in size from that of a nut to a walnut. The tingling sensation excited in the ear when it was applied to the back of the right side of his chest, during the act of speaking, was quite painful. I

will not pursue this subject further, nor will I, on this occasion, enter upon the consideration of those modifications of the voice which are observed in pleuritic effusion; I am, however, engaged in making experiments on the propagation of sound through different media, the results of which will, I trust, throw some light upon this subject.

The following conclusions may, I think, be deduced:—

1. That the respiratory sound is caused by the friction of the air against the interior of the air-passages, and that it becomes softer and weaker from the mouth towards the periphery of the lungs, owing to the divergence of sound caused by the great space over which it is spread, and to the diminution in the calibre of the air-tubes.

2. That the sound of *vesicular respiration*, confined almost entirely to the time of inspiration, is *principally* generated in the bronchial tubes, and would be scarcely perceptible to the ear at the surface of the chest, were it not borne up to it by the current of air during inspiration.

3. That the coarse respiratory sound, heard both during the inspiration and expiration over a solidified portion of lung, is generated in tubes leading to healthy expansible vesicles, and is made sensible to the ear by its being brought into immediate contact with their sides by the solid lung.

4. That the timbre of wind-instruments and of the vocal apparatus depends on the proportion in which the solid vibrations of the material of which they are made are united with those of the air within them, becoming coarser as the former predominate.

5. That in accordance with this law, the voice sounds coarser and buzzing through a stethoscope placed over the larynx, because its vibrations are propagated more freely to the ear through the solid material of the instrument (a similar medium) than through the air contained within it.

6. That the resonance of the voice diminishes from the larynx to the periphery of the chest, where it ceases, from its vibrations being gradually stifled by the opposing current of air during expiration, and by the increasing mass of spongy non-homogeneous lung.

7. That in certain diseases resonance of the voice is perceived at the surface of the chest, owing to the current of air

being weakened or destroyed, and the conducting power of the lung increased; and that its timbre is altered in proportion as the propagation of one or other of its component vibrations is favoured or retarded by such morbid changes—the aerial undulations predominating in cavities, and giving rise to clear pectoriloquy, and the solid undulations predominating in solidification, and producing buzzing bronchophony.

#### MISCELLANEOUS CONTRIBUTIONS

TO

#### PATHOLOGY AND THERAPEUTICS.

##### CONTRIBUTION II\*.

By JAMES RICHARD SMYTH, M.D.

[For the London Medical Gazette.]

*Case of chronic hydrocephalus in which the operation of tapping was practised; with remarks.*

Nov. 28th, 1835.—Edward Saunders, aged 5 months, was born at the natural period of gestation, and at birth appeared to be strong and healthy. He throve well until attacked by small-pox, which occurred when he was about five weeks old. He passed through that disease pretty well; but about a fortnight or three weeks after he was seized with severe griping pains of the bowels, and inward fits, accompanied with dark slimy discharges from the bowels.

About this time, or shortly after, the child's head was first perceived to be larger than natural, and its volume has continued slowly to increase up to the present period. During the last month he has been taking occasionally a little aperient medicine. His present condition is as follows:—surface, generally, pale and chill; there is not much emaciation, but the flesh is soft and flabby; pulse regular, but frequent and weak; bowels regular, and their excretions healthy. Urine very copious. The parents state that they consider the child passes at least three pints in the twenty-four hours. He frequently makes water three or four times whilst at the breast, and he has been observed to wet five or six napkins during the course of the night. Appetite good; tongue clean; sleep disturbed by frequent startings and

\* For No. 1, see MED. GAZ. Vol. xx. p. 79.

sometimes screaming: violent and frequent oscillation of the eyes, pupils *not* dilated, no vision, and senses of taste and hearing almost extinct. Cranium much enlarged; its measurement as follows:—Circumference from the forehead to occiput twenty-two inches and a half; from each meatus auditorius over the vertex, fifteen inches and a half. The coronal, sagittal, and lambdoidal sutures, are all very open, and in any of these tracts the fluctuation in the interior of the head can be easily detected by the sense of touch. There are not the slightest cerebral movements or *cerebral murmur* present. The veins of the scalp are all unusually large and apparent, and

there is scarcely any hair. After having had the bowels cleared out once or twice by infusion of senna, with manna, the following powder was ordered to be taken every sixth hour.

R. Hydrarg. Submur. gr.  $\frac{1}{2}$ ; Sacch.  
Alb. gr. ij. ft. pulv.

December 1st.—Has taken seven powders. Frequent slimy and greenish discharges from the bowels. The mother considers that the child does not pass so much urine since he commenced to use the powders. He is also more restless, somewhat feverish, and he has had several attacks of sickness and vomiting. In other respects no change.

Continuentur Pulveres.

4th.—Has taken eight more powders. The child has been more lively and has rested better during the last day or two; he has not screamed or started so much in sleep. The alvine excretions are still very frequent, and vary in colour from that of wet chalk to green. Pulse and skin at present pretty natural; but the mother states that the temperature of the head is changeable—that it is sometimes very hot, and at other times equally cold. Size of head unaltered, oscillations of eyes scarcely so violent; pupils as before; no sickness.

Continuentur Pulveres. Let a tea spoonful of an astringent mixture, composed of Infus. Catechu Comp., with a few drops of the tincture of opium, be taken with each.

6th.—Has taken the powders and mixture regularly since last report. The excretions from the bowels still rather frequent and greenish. Urine much less copious, considered to be natural in quantity, pulse quick and feeble, but regular, tongue clean, surface chill. Great restlessness both during the night and day, oscillation of eyes very violent, bulk of head increased fully an inch in the transverse measurement, and three-fourths of an inch in the circumferential; no anorexia.

Continuentur Pulveres i. ter in die, et mistura pariter continuentur.

8th.—No appreciable change either local or general since last examination. The medicine has been used regularly, but no constitutional effects from the mercury are yet manifest.

R Hydrarg. Submur. gr. viij.; Sach.  
Alb. gr. xij. M. et divide in pulv.  
sex æquales quarum sumat. i. 8ta.

FIG. 1.

FIG. 2.

99. horā. Habeat statim balneum calidum.

9th, 5 o'clock P.M.—Has taken three of the last ordered powders. The child has had frequent attacks of retching and vomiting this morning. At present there is frequent and troublesome dry cough, with anorexia, dyspnœa, and restlessness. Surface and extremities chill; pulse quick and feeble; otherwise no change.

Let a drop of the sedative liquor of opium, with a little syrup and tincture of cardamoms, be taken immediately, and repeated every fourth hour till the retching and vomiting cease. Intermittantur pulveres, sed balneum calidum statim repetatur.

10th.—Had a fit of insensibility last night between 11 and 12 o'clock, which lasted three quarters of an hour; while this fit was present the child was so prostrate and cold that the parents considered him dying. The cough is still rather troublesome, but the dyspnœa and attacks of vomiting are much less urgent; pulse frequent, feeble, and intermittent; alvine excretions still greenish, but more natural in quantity. Scarcely any urine passed since yesterday; no alteration in condition of head since the report of the 6th.

12th.—The general condition of the child has improved considerably during the last two days: there has been no return of insensibility, and the dyspnœa and sickness, with the other signs of prostration, have disappeared. The urinary secretion is re-established. Pulse, skin, and excretions from the bowels, more natural; no change in condition of head.

Intermittantur omnia medicamenta.

March 15th.—Had not seen the child now for the space of three months. In all respects little or no alteration since last examination. On applying a piece of tape to the head its volume was found to be exactly the same as when last measured. Appetite good, bowels said to be regular, and excretions of a healthy appearance; diuresis still continues. The mother states that she has observed the child to make water 36 times from 6 o'clock yesterday evening, till 7 o'clock this morning. Two incisor teeth are just protruding in the lower jaw. No medicine prescribed.

April 17th.—The child has had frequent attacks of slight convulsive fits during the last fortnight, which have

been chiefly confined to the eyes, muscles of the face, and the arms. The head has rather increased in size, and the hair has considerably grown during the last month. Appetite good; sleeps well; pulse pretty natural; bowels regular; diuresis as before. No medicine prescribed.

June 8th.—The size of the head continues to increase, and two small tumors have formed on its lateral and posterior part in the course of the lambdoidal suture. There is also considerable emaciation, and the child has now frequent attacks of violent and general convulsions, which alternate sometimes with fits of general tension of the body. Stupor and oscillation of eyes continual and intense; vision, pupils, and senses of hearing and of taste, as before stated; much starting and grinding of the teeth in sleep. Pulse feeble, frequent, and irregular; urine very copious and limpid; surface chill.

Seeing that we had failed to effect any improvement in the condition of the child by the mercurial treatment, and having little dependence, under the existing circumstances of disease, in any of the other alteratives generally in use, we thought it right at once to have recourse to the operation of tapping the head, and to-day, at 2 o'clock, P.M. after having placed the child on its back on its mother's lap, and the hair having been closely removed from the site of the operation, a short longitudinal incision was made with the lancet through the scalp down to the dura mater, a little to the left and about half an inch behind the anterior fontanelle, and a fine trochar and canula introduced to the lateral ventricle: 4 ounces of clear water were drawn off, a piece of lint applied to the wound, and the head tightly bound up with a flannel roller. The child immediately after the operation became faint and pale, and experienced a slight convulsive fit, which was confined to the muscles of the face and arms. No medicine prescribed.

9th, 1 o'clock P. M.—Spent a quiet night. He turned upon his face during the night, and the bandage and compress came off the head, but no water escaped from the wound. Had two severe fits of convulsions this morning. From the time the operation was performed till 12 o'clock, midnight (10 hours) the child made water only four

times. Has made water very frequently this morning; the wound of the scalp has healed, and the head seems as full and tense as before the operation was performed. Tongue clean; bowels regular; pulse undisturbed; no medicine prescribed.

13th.—No very appreciable change since the 9th, except that the head, in both measurements, appears to be from a quarter to half an inch less.

Repeated the operation this morning, in the manner already described; the trochar having been introduced about a quarter of an inch from the former puncture, six ounces of limpid water were drawn off. Towards the close of the operation, as the fluid continued to escape, the vertex became considerably concave, and the child pale and chill, but did not as before manifest any signs of convulsions. The incision in the scalp bled more freely at this operation than at the former one. After the bandage was applied to the head the child appeared endeavouring to look about him with some consciousness and surprise of countenance. The mother states that during the last day or two he is more lively, and more disposed to exercise his arms; these (what he had not before been able to do) he has once or twice raised to his mouth: otherwise no change. No medicine prescribed; but let the child be as much as possible in the open air, and let him have some beef-tea three or four times a day.

14th, 11 o'clock A.M.—Passed a quiet night. Condition of the child in all respects much the same as yesterday, except that the circulation and vital powers are rather more depressed. The vertex remains concave, and the brain collapsed as immediately after the extraction of the water. The dropsical effusion appears to have been suspended during the last 24 hours. Refuses the breast.

To have a warm bath immediately, and occasionally a little cordial medicine.

15th.—Had the bath, but no effect appeared to be produced by it. The child spent a feverish and restless night; skin, at present, hot and dry; eyes dull, and their oscillations languid. There is a slight patchy exanthema on the shoulders and front part of the neck; pulse rapid and irregular; urine scanty; bowels confined; refuses the breast, but takes a little milk and water when put into the mouth. Vertex remains con-

cave, and brain collapsed; no grinding of the teeth, but much moaning during sleep.

R. Hydrarg. Submur. gr. iij; Pulv. Antimon.; Sacch. Alb. aa. gr. vj. M. et divide in partes sex æquales quarum sumat. j. 6tis horis.

R. Vin. Antim.; Vin. Ipecac. aa. ʒj.; Syrup. Simp. ʒij.; Aquæ Carui. ʒj. M. fiat mist. cujus capiat coch. parv. ij. secunda quaque hora.

16.—Spent a better night, and is not so hot or feverish as yesterday. Exanthema still present, and vertex still concave, and brain collapsed. Two or three greenish discharges have been passed from the bowels; in other respects no change.

Continuentur medicamenta.

18th.—Considerable improvement in condition of child to-day. The pyrexial symptoms have nearly subsided, and the exanthema has entirely disappeared. Skin, pulse, and state of bowels, more natural; sleeps better, and is less disinclined to use the breast; vertex remains concave, and brain collapsed.

Continuentur medicamenta.

26th.—Little or no alteration in the condition of the child during the last eight days. The vertex is still slightly concave; the circumferential measurement of the head has increased an inch; the diuresis has returned.

Intermittantur medicamenta.

July 7th.—Head again much distended and tense, and the child has frequent fits of general convulsions; there is also much stupor and oscillation of eyes; otherwise as before; appetite good. Operated again to-day. The puncture was this time made on the right side of the longitudinal sinus, and the trochar introduced to the corresponding lateral ventricle. The scalp bled rather freely, and the child appeared, from its screams, to have experienced considerable pain during the introduction of the instrument. Six ounces of clear water were drawn off, and the roller as before applied to the head. The system did not appear in the least affected by this operation; no manifestations of either syncope or convulsions followed it. The child sneaked during the time the water was escaping, and seemed altogether unconscious of what was going forward. No medicine prescribed; but let the child have a little beef-tea or arrow-root

three or four times a day, and let him be as much as possible in the open air.

We made a visit late in the evening, and were not a little surprised to find that the head was almost as full and tense as in the morning, before the operation was performed.

8th.—Spent a good night; the child is evidently improving; he is becoming lively, and the stupor and drowsiness are disappearing; there is also more freedom of motion of the head and limbs; no return of convulsive fits since yesterday; the oscillation of the eyes is still violent, but some improvement is discernible in this phenomenon; the motion of the eye is much less languid, and the duration of the writhe less prolonged. Tongue clean; pulse and skin pretty natural; bowels regular; urine not copious. He takes his beef-tea.

*Continuentur remedia præscripta.*

18th.—The size of the head has slightly increased during the last ten days, and the vertex is now quite distended and tense. The general health and condition of the child is much improved. The little patient is remarkably animated and lively; he now laughs frequently, and is conscious of and much pleased with being caressed. The convulsive fits have entirely ceased since 7th instant. He is very fond of being out of doors in the open air, and he seems to derive some pleasure (perhaps benefit) from pretty tight friction of the scalp with the hand, which the mother has been in the habit of performing for some time back, and which we have ordered to be continued, and repeated frequently during the day. Pulse, state of bowels, and skin, pretty natural; diuresis again present.

Punctured the head to-day again, and allowed seven ounces of clear water to escape. The child screamed loudly during the introduction of the trochar, of which he appears more acutely sensible at each succeeding puncture: some retching and vomiting followed the operation. The roller, as before, was applied to the head; no medicine prescribed; but continue the present diet and regimen, with the friction of the scalp.

21st.—Going on extremely well; no febrile movement followed the operation; the child has been playful and in high spirits during the last three days. The water has already reaccumulated in the head, which is now quite full and tense.

In the manifest improvement, however, of the general health, the condition of the brain has obviously much participated. The insensibility and sleepiness, and every other indication of cerebral oppression which hitherto existed, have entirely disappeared. The child is now very vigilant and can exercise his senses; he listens to every sound, particularly that of the voice, with remarkable attention, and turns his eyes towards the direction whence it proceeds. The eyes are more steady, and with the countenance altogether more lively and intelligent. Pupils as before *not* dilated, but, if any thing, slightly contracted and quickly obedient to the light, to the presence of which the mother thinks the child itself is now in some degree sensible. The sutures of the skull are considerably less open, which results not from diminution of the size of the head, but from advancement of ossification and increasing volume of the cranial bones. The flesh also is more firm, and the body and limbs more plump and round. Appetite good, sleeps well, no return of fits, bowels regular, diuresis still present.

*Continuentur omnia remedia.*

August 2d.—Little or no alteration in any respect in the condition of the child since last report. The ossification of the cranial bones has progressed a little, and the size of the sutures is still further lessened. Two incisor teeth have made their appearance, one in the upper and one in the lower jaw. Operated, and drew off twelve ounces of clear water. Drs. Baird, R. Routh, and one or two other medical gentlemen, were present. No retching or faintness followed the operation. Being desirous of giving mechanical support to the head more efficient than that afforded by the roller, we had a sort of many-tailed tourniquet bandage\* constructed, which was now applied, and by means of which the cranial bones could be so pressed together and approximated as to be brought into complete contact, although at some points they were from an inch and a

---

\* This bandage answered its object very well. One broad strip of it embraced the head longitudinally, the others vertically. On the former, besides a buckle, was fixed a screw like that of a tourniquet; to the latter were attached merely buckles: on applying the instrument moderately tight to the head by means of the buckles, by a few turns of the screw the head could be compressed to any extent thought requisite.

half to two inches apart. Continue the present diet and regimen.

We visited the child in the evening, and found him lying on his side in bed, and in a playful manner muttering to himself.

4th.—No change during the last two days, except that the head is again half distended; tightened the bandage, which had become a little slack.

6th.—Had a restless night, and has been retching and vomiting frequently this morning. Skin hot and dry; pulse quick; urine scanty and high coloured; little appetite; bowels confined; the head remains in the same state of distension as on the 4th.

To have an aperient powder immediately, and occasionally a little febrifuge mixture.

8th.—The pyrexial symptoms have all disappeared; appetite returned; diuresis again present; head full and tense; considerable emaciation of the body and limbs during the last few days, and the ossification of the cranial bones does not appear to be progressing. The child is becoming peevish and listless, but he is still fond of being out-of-doors in the open air, and he takes his beef-tea regularly.

10th.—No improvement or appreciable alteration during the last two days. Punctured the head again. Dr. Baird and Mr. Vance were present, and suggested that the whole of the water should be drawn off. The trochar was introduced close to the cicatrice of the last wound, and between 16 and 17 ounces of clear water escaped. At the close of the operation the child became faint and pale, and vomited two or three times. A few teaspoonfuls of a cordial mixture were administered, which immediately revived him. The head now presented a very singular appearance. The scalp was quite loose and flaccid, and the vertex formed the floor of a deep concavity, at the bottom of which the feeble pulsatory movements of the brain were just perceptible to the touch. By the advice of Mr. Vance, the tourniquet bandage (the pressure of which had caused one or two small spots of inflammation on the scalp) was now discontinued, and the flannel roller resumed.

Continuentur diæta et alia remedia.

11th.—Had a good and quiet night, but has been retching and vomiting this morning; occasional starting and raising of hands to head; skin rather hot, pulse

frequent, urine scanty, bowels confined, but appetite not deficient. Vertex still concave, but less so than yesterday. Otherwise as before. Let the child have a little castor-oil immediately, and let five grains of strong mercurial ointment be rubbed upon the thighs every night at bed-time.

Continuentur alia remedia.

14th.—The ointment has been rubbed in three times, and the child has been very irritable and peevish during the last two days; his sleep also has been disturbed by frequent startings; little appetite, diuresis as before, head full but not tense, bowels free.

Continuentur unguentum et alia remedia.

22nd.—The parents have discontinued the use of the ointment, as the child has not been able, for some days, to use the breast, in consequence of soreness of the lips and tongue. These parts are at present covered with a thick crop of aphthæ. On applying the tape to the head its size was found to be exactly the same as when first measured, viz.  $22\frac{1}{2}$  inches by  $15\frac{1}{2}$ ; otherwise no change.

Operated for the seventh time, and drew off 12 ounces of straw-coloured water, which did not appear to affect the child in the least. Roller applied to the head as before.

Unguentum intermittatur sed continuentur diæta et regimen. Let the child be removed for some time into the country.

September 30th.—The child has been in the country during the last five weeks, which has not been productive of any improvement in his condition. The head, indeed, appears now larger and more tense than we have ever seen it, and the trunk and limbs are more emaciated. Countenance dull and oppressed. Oscillation of eyes violent; and he has lately experienced one or two rather severe fits of general convulsions. Diuresis urgent. Appetite good, and continues to take his beef-tea with eagerness. In other respects no change.

Punctured the head again, and extracted 28 ounces of straw-coloured water. No signs of faintness or manifestation of suffering from this operation.

Perset ut antea.

October 3d.—Was very restless, and had several fits of slight convulsions, the night following the operation. The next day, however, the child was better, and tranquil, and has continued so till

the present time, without any return of the fits. The water, to a considerable extent, has reaccumulated in the head: in other respects the same.

Perstet ut antea.

12th.—Head much distended and tense, and from the progressing emaciation of the trunk and extremities, appears now unusually large. The stupor and dulness of hearing, though less intense than before, are again present, and the oppression of the countenance is increasing. No return of the convulsions, and pupils still, as first described, *not* dilated. Surface chill, pulse weak, and very quick; urine profuse.

At the suggestion of Dr. Baird a puncture was now made in the back part of the head, the trochar being introduced in the course of the lambdoidal suture, to the left of the *os triquetrum*. 42 ounces of clear water were drawn off, and the child did not appear in the least affected by it. Roller tightly applied to the head.

Let the child have a teaspoonful or two of a cordial mixture occasionally.

13th.—Spent a restless night. The vertex remains concave, and brain collapsed as after the operation, and the condition of the child, in all respects, much the same as yesterday. No convulsions. Appetite pretty good, and sucks often.

Let a little boiled milk, with arrow-root, be substituted for the beef-tea.

15th.—No change in the condition of the child during the last two days, except that the head is again nearly full.

As we were rather dissatisfied at the manner in which the calomel, administered at an early period of the treatment, had disagreed with the little patient, we now felt disposed again to try the effects of the medicine, and considering that the pressure of the water on the brain had, in the first instance, interfered with its absorption, and constitutional action, to obviate this circumstance a puncture was a second time made in the course of the lambdoidal suture, and twenty ounces of clear water extracted. The following powder was ordered to be given to the child every sixth hour:

℞ Hydrarg. Submur. gr.  $\frac{1}{4}$ ; Pulv. Ipecac. comp. gr.  $\frac{1}{8}$ ; Sacch. Alb. gr. j. Fiat pulv.

16th. 1 o'clock P.M.—Three of the

powders have been taken, and three or four thin light-coloured evacuations have been passed from the bowels. The night has been spent in restlessness and whining. About 5 o'clock this morning the child fell asleep, since which time he has remained quiet and silent. At present he appears to be in a semi-comatose state. There is violent oscillation\* of the eyes, with frequent grinding of the teeth; considerable tension of the extremities; skin dry and hot; tongue dry; pulse very rapid and irregular; respiration hurried and heaving; anorexia, with immediate vomiting when any thing is taken into the stomach; urine very scanty; vertex concave; and brain collapsed.

17th.—Had an attack of general convulsions about 9 o'clock yesterday evening, which was repeated at longer and shorter intervals till 3 o'clock this morning. He died at 4, an hour after.

*Dissection, eight hours after death.*—Great and general emaciation. On laying open the head by a crucial incision over the vertex, the dura mater presented its usual healthy appearance; the arachnoid membrane was of a pinkish hue, and its vessels gorged with blood

\* *Writhing*, perhaps, would be a more appropriate term than oscillation for this morbid motion of the eyes, which evidently is not, like that of a pendulum, from which the term seems to have been transferred, either mechanical or uniformly lateral. In the case just related, the eyes, though almost in continual lateral motion, were sometimes turned downwards; but what appeared to us remarkable, we never once saw them directed upwards. As an instance of the discordance which in some points not unfrequently occurs in the general description of a disease, and the phenomena of individual cases, we shall give a short quotation from Dr. Copland's Dictionary of Practical Medicine (Part III. p. 677), describing the condition of the head and the senses, and more particularly the eyes, in his third variety of chronic hydrocephalus—that to which the present case belongs. "When the cranium is very much enlarged, the countenance presents a nearly triangular form, owing to the bones and the lower features of the face retaining their natural size, or being smaller than usual. As the disease proceeds, the sutures are more and more separated, sometimes so far as to admit of fluctuation being felt, as remarked by Tulp, Dreyssig, Monro, and others. The veins of the neck become enlarged (Lentin saw them varicose), the carotid arteries pulsate with much force, and the head generally hangs on one side, or on the breast. Owing to the unequal yielding of the cranial parietes, some one part of the head is occasionally more prominent than another. The eyes are generally watery, covered by the eyelids, the pupils dilated, directed upwards, occasionally downwards (Feiler, Goetis, Schmidt) and sometimes horizontally to either commissure of the eyelids. The senses, the intellectual faculties, and the locomotive organs and functions, betray more or less disorder. Sight is first impaired, and all the other senses subsequently fail."

of rather an arterial colour: the convolutions of the cerebrum were completely obliterated, and this division of the brain formed a large double cul-de-sac, smooth externally and internally, which contained four pints of clear water; the lateral ventricles, and also the third, in which this fluid had collected, communicated by an opening almost as large as the foramen of Winslow in the peritoneum, the septum lucidum and the fornix being absent, either from morbid destruction or non-development: the serous membrane lining the entire of this cavity was somewhat thicker and less transparent than natural; its veins were much enlarged, and their course, converging from the circumference to the centre, was beautifully conspicuous. The plexus choroides were large, and of a drenched appearance. The cerebral substance was much softened, and very thin. On the upper part of the anterior lobes it was little more than a line in depth; its thickness increased in the middle and posterior lobes. There were no appearances either in the brain or its membranes from which it could have been inferred that inflammation to any extent had followed any of the punctures. The situations of three or four of these were marked by little cicatrices or white lines in the cerebral substance, similar to those which remain on the arm after venesection. The arachnoid membrane and pia mater at the base of the brain were much thickened, and also covered by a deep incrustation of stratified lymph, which exhibited a difference in colour and consistence, as if its effusion had taken place at old and recent dates. On removal of this lymph with the subjacent membranes, the cerebral nerves, white and healthy-looking, were seen issuing from their respective origins. No tubercular deposits\* of any sort were found either in the cerebral substance or its meninges. The condition of the cerebellum appeared pretty healthy. Weight of the cerebrum and cerebellum, with a portion of the medulla oblongata, 1 lb. 10½ oz. These, after the whole of the water was removed from the cranium, did not occupy more than between a third and fourth of its cavity. No other part of the body was examined.

Total 217

This water during the course of the treatment was several times tested in the usual manner by heat and an acid, but no trace of albumen was detected.

In the treatment of this case of chronic hydrocephalus, although we were not so successful as to have established a cure, nevertheless we must claim some credit for the therapeutic measures employed, in having effected, for a time, considerable and manifest improvement in the condition of the brain, and also in the general condition and health of the child. In combating disease, (let us here observe), especially if of an intractable and destructive nature, when from the peculiarities of the case it may be deemed fit to have recourse to remedial means of doubted or disputed reputation, though death, as in this instance, should ultimately supersede our efforts, it must still be satisfactory to know that, by these, an amelioration of symptoms, and some prolongation of life had been obtained. We are fully aware of the difference of opinion which generally prevails regarding the results, whether beneficial or otherwise, of tapping the head in this affection; and several of the facts that have been urged on both sides of the question we had an opportunity of witnessing during the progress of the present case; to a few of which, with some other points in its pathology, we mean now briefly to advert.

It is scarcely necessary to state that we are advocates of the operation, and on this account naturally feel the more disposed to draw attention chiefly to those circumstances in the treatment of the case which must evidently be considered commendatory of the measure.

---

\* We allude to the appearances lately disclosed in some interesting papers on infantile pathology, by Dr. P. H. Green.

Look at the condition of the child when it first came under our care, and during the early medicinal treatment, and compare this with that which it presented from the third until after the sixth operation. What a happy alteration in all respects did not the state of the little patient exhibit during this latter period! and to what was it attributable? Solely and simply to the relief afforded to the brain by the removal of the incumbent fluid. Observe the great amendment which had taken place not only in the cerebral functions, but also throughout the entire extent of the animal and organic systems. The attacks of convulsions had ceased; the stupor and drowsiness had disappeared; sensibility and voluntary motility had returned; the senses were resuming their functions, and the development of the mental faculties had actively commenced. The sense of hearing, as we have seen, from having been almost extinct, had become remarkably acute; vision also to some extent had returned, and the expression of the eyes and of the countenance altogether was considerably improved and more intelligent. The circulation, too, had become more diffused and equable, and the functions of assimilation and of nutrition were more healthily performed. These latter amendments, vital and important, as will be granted, were very manifest in the much less anæmic appearance of the cutaneous circulation in general, and that of the scalp in particular; and by the plumpness and firmness which the body and limbs had acquired, and also by the progressing ossification of the cranial bones. Up to this point matters could scarcely have gone on more satisfactorily, or more to the credit of the operation; but after the seventh tapping, when the child was ordered into the country, we had relinquished, we acknowledge, all hopes of its recovery; and the subsequent punctures and other remedial measures were had recourse to more with the object of alleviating symptoms, and mitigating suffering, than from any hope we then entertained of effecting a cure. It has been seen, however, that the extent to which the water had accumulated in the head during the child's stay in the country had brought on a return of the convulsions, and that these inauspicious symptoms, on the removal of the fluid, again subsided, and did not return till a short time previous to death. This fact,

of itself, as it contains some therapeutic instruction, is not undeserving of a little attention. And, though not altogether in place, we are tempted here to remark that it cannot be the part of a diligent physiologist, or of a humane and attentive physician, to permit his prognosis, however unfavourable it may necessarily be, either to impair his interest in the terminating phenomena of disease, or interrupt his solicitude in administering whatever relief his art or his anxiety might suggest. With us, unquestionably, there is no period in the progress of human suffering which more fully engages our attention, and from which, we conceive, we derive so much information, as the period now referred to, namely, the latter hours of fatal illness. Is it not, we would ask the student of the bedside, at this particular time, during the co-existence of disease and incipient dissolution, as the symptoms of the former are gradually being obscured in the signs of the latter, that human pathology becomes most analytical, and develops some, nay, many, of its most impressive and instructive facts, and therefore that much critical and practical knowledge of the direct dependencies of the several vital functions may be obtained by attentively observing the order in which their lesions rapidly supervene, together with the increasing difficulty with which life is sustained, as these become more and more numerous? We would willingly continue our observations on this point, but it would detain us from our subject.

We have said that we are advocates of this operation: we shall state our reasons. They are these: we advocate it, 1st, from the number of cures which it is reported to have produced, and we are satisfied it has done, in the hands of other and more experienced operators.

Dr. Conquest in this country, and Gracfe on the Continent, have published some cases in which they seem to have been singularly successful. 2nd, from the very manifest benefit which we ourselves observed to result from it, in the present aggravated, and, as was considered, hopeless case. And 3d, from the obvious rationality of the measure, as it would appear to us, when had recourse to at the proper period, and under the particular combination of lesions, which ought indeed, we conceive, *per se*, to indicate its application. When the head, as in the case under considera-

tion, has become so enlarged that its appearance altogether might bear some resemblance to that of a small balloon, and the coronal and sagittal sutures are from one to two or three inches asunder, and when over these parts the scalp has become so distended and tense that it has acquired a smooth and shining surface, and further when the touch here can discover no cerebral motion, but can easily detect the subjacent fluid, and if (as no doubt generally is the case) with this set of physical signs, coma, insensibility, and perhaps convulsions be joined, no reliance on general expedients should, in our humble opinion, delay for a moment the employment of the trochar. This case, it may be mentioned, had been under the care of several medical men, and had undergone a variety of treatment before we saw it, but no means that had been adopted had afforded any relief, or indeed produced any effect in the disease. The tapping alone wrought the first change; which change, seconded by the nutritious diet of beef-tea, and the salutary exercise in the open air, we had every expectation, for some time, would have gone on to a perfect cure. To what we are to attribute the cause of the relapse it is difficult to say. The parents latterly became impatient and negligent, and the child in consequence did not receive the attention we should have wished.

As a good example of the pathological sympathy which is frequently manifested between the brain, under some states of disorder, and the functions of the kidneys, we would instance the diuresis that was present in this case, and the manner in which it was immediately influenced by the removal of the water at each operation. At these times, indeed, it appeared to us that a sort of metastatic connexion existed between the sudden diminution of the renal secretion, and the rapid simultaneous reappearance of the cerebral effusion.

Is it not a circumstance of some curiosity and interest, and somewhat difficult to understand, that the improvement which took place in the general health and condition, and also, as we have seen, in the state of the brain itself of this child, was not, as might have been expected, accompanied by a simultaneous reduction or return to a more natural size of the head, or, in fact, any abatement of the dropsical accumulation? The head certainly, on measurement,

was found to have varied a little in dimensions two or three times during the course of the treatment; but this, it seemed to us, was not owing to any thing otherwise than a casual modification in the state of the effusion; for we actually observed, not without considerable correction of our preconceived ideas on the matter, that during the period when the child's condition, externally in all respects, was most of all improved and improving, at that very time, on occasion of the removal of the water from the head, the distension returned with the greatest celerity: what explanation are we enabled to offer of phenomena so seemingly discrepant?

If we criticise with attention the salutary alterations which our treatment had effected, will it not be perceived that the greater part, indeed that all of them, can be traced to a more active and healthy performance generally of two or three of the organic functions, namely, circulation, exhalation, and nutrition? and that it was simply to our having succeeded to a considerable extent in arousing these primitive principles, simultaneously with their increased activity in other parts, to a more energetic state of action within the cranium, that we were indebted for the temporary revival of the cerebral functions themselves, properly so called, *i. e.* sensation, motion, and intellect; and that we must also attribute the cause of the continuance of the hydropic effusion. The proximate cause of the disease, we are disposed to think, was seated not in the arterial but in the venous side of the cerebral circulation, and involved a defect in the function of absorption, and notwithstanding the reaction and approach to a more normal condition which were manifested, for a time, in the state of the brain, its animal, and also its organic functions above mentioned, this lesion of absorption remained unrepaired from first to last, which, we have no doubt, was the reason of our ultimate failure in effecting a cure.

The principal ill consequences which have been placed to the discredit of the operation, are inflammation of the substance of the brain or its membranes, and cerebral collapse. Of the former, mechanical injury by the trochar has been considered the cause. But our experience in the case under consideration would lead us to doubt the entire correctness of that opinion; for, on re-

ference to the dissection, it will be found that the vicinity of the punctures were exempt from all inflammatory results, but that these were located at a different part of the brain—namely, at its base. These facts have induced us to think, that perhaps in this case it was not so much the puncturing of the brain as the consequent collapse of the organ, which gave rise to its several attacks of inflammation; and this opinion, it may be allowed, receives more than a little corroboration by our having observed, during the treatment, that the symptoms of cerebral inflammation, and the state of cerebral collapse, were always concomitant; that after each operation, although the brain necessarily became more or less collapsed if that state continued longer than twenty-four hours, it was afterwards accompanied by general febrile excitement and symptoms of cerebral inflammation; and that on the disappearance of these, the dropsical effusion was again quickly repeated, and the brain rendered distended and tense. Such phenomena we observed not only once, but three or four times; and the mode in which it would occur to us to explain them, would be, that under the condition of collapse, the mass and weight of the brain, instead of being supported, and pressing, as in the healthy state of the organ they naturally do, on the sides as well as on the base of the cavity of the cranium, pressed wholly on this latter part, thereby producing more or less obstruction of the circulation, with some degree of irritation of the interposed membranes, on which the inflammatory attacks supervened; that during the existence of these attacks, and more especially of the sympathetic febrile excitement, owing to, and concomitant with, the *general* arrest of secretion and exhalation which accompanies and characterizes such a state of the system, the *local* effusion in the present instance was suspended, and the brain, in consequence, remained collapsed. But, as has already been remarked, as these inflammatory and febrile states disappeared, and the processes of exhalation and secretion generally resumed activity, the dropsical effusion was speedily repeated, and the brain rendered distended and tense. If this explanation be correct, what is the instruction, and what are the practical indications, which it contains? Does it not point to the

propriety, in performing the operation, of using every precaution to avoid the occurrence of collapse?—and that, it appears to us, can only be done by extracting the water slowly and in small quantities: from four to six ounces is the most, we think, that should be drawn off at a time.

The practice by acupuncture, recently had recourse to in the treatment of other species of dropsy—namely, hydrocele and ascites—might, perhaps, be beneficially applied to chronic hydrocephalus, and, as we think well of it, we intend, in the first case like the present which may come under our care, requiring to be operated upon, to give it a trial. A few words more in conclusion.

In a former paper\*, in which we described three cases of cerebral disease in children, which we considered to be cases of chronic hydrocephalus in its first stage, we pointed out the presence of a murmur or sound accompanying the cerebral pulsations, audible on the application of the ear to the anterior fontanel and parietal bones. In the case we are now considering, it is well worthy of notice, though a similar affection to those to which we allude, but in a different and more advanced stage of its progress, this auscultic phenomenon was entirely absent. And why? Because, in fact, the diseases, though similar in names, were very different in their pathological natures. In the cases of Crispin, Long, and Moore, in the paper above referred to (which, regarded as cases of chronic hydrocephalus, should perhaps be viewed as more in their causes than actually formed), considerable excitement of the circulation and increased action of the vessels of the brain, which appears, indeed, to belong to the earliest stage of the malady, and from which the sound evidently results, were present. But not so in this case of Saunders: here the disease was in its fullest state of development; its pathology had run its course complete, and had passed beyond the point at which, if the child's head had been auscultated, the sound in question would, no doubt, have been detected. Here the cerebral circulation, instead of being excited and accelerated, had become depressed and languid almost to arrest, and the usual pulsatory movements of the brain had altogether ceased.

\* Medical Gazette, Aug. 19, 1837.

As a diagnostic sign of chronic hydrocephalus, in its most incipient state, that state obviously in which remedial measures can be had recourse to with most hope of success, we are much disposed to think this cerebral murmur will be found of considerable practical utility; and as an instance in point, we will here state a case which has occurred within the humble range of our own experience. Nearly three years ago, Mr. McCay, then of Stewart Street, Bishopsgate Street, a fellow-student of ours, whose attention we had drawn to the existence of this sound in the heads of some children, requested us to examine a case with him, in a Court behind the Bank, of a child of the name of Griffiths, between two and three years old. On examination, we found the child drooping, peevish, and pale; its flesh soft and flabby; its abdomen larger than natural; the bowels irregular; its sleep disturbed; some thirst, and occasional complaint of headache. The head did not appear in any degree enlarged, but the anterior fontanel was still open, and its pulsations more heaving than natural; and, on applying the ear over the part, the subjacent sound was very audible. We at once expressed our apprehension to the mother that the indisposition under which her child laboured was dropsy of the brain, commencing or already present, and prescribed accordingly. We did not see or hear any thing further of the child for about two years, at the end of which time, to a day or two (not having a case of the disease then in our own practice), we went in search of it, and to our surprise found it; and how?—just moribund; with its head enormously enlarged and full of water. We learned from the parents, that, from the time we first saw this child, its general health never shewed any signs of improvement, but gradually became worse, and its head commenced to enlarge; that up to the time of its death it had been continually under medical care, but without having experienced any satisfactory relief from any treatment which was adopted. No operation was performed.

In the paper which we have already referred to, we took occasion to mention that we thought some analogy might be perceived to exist between the condition of the brain and its circulation, during the presence and absence of this cerebral sound in chronic hydrocephalus,

and the condition of the lungs or lung, and its respiration, during the presence and absence of the respiratory murmur in the diseases of empyema and hydrothorax. When we began to operate upon the child, the idea occurred to us, that if the treatment should prove successful, as the cure advanced and the quantity of water in the head gradually diminished, we might probably have an opportunity of observing the disease, in some respects, retrace its steps—of witnessing, for example, the resuscitation of the cerebral pulsations, and redevelopment of the cerebral murmur; just as, after the operation of tapping the chest for empyema or hydrothorax, is frequently observed the re-expansion of the compressed lung, and the redevelopment of its respiratory murmur. But such was not the case. The disease, as we have seen, in spite of all our exertions, proved fatal. Whether, if it had been otherwise, and, instead of the improvement that was produced, a cure had been effected, we would have had the satisfaction of witnessing the confirmation of our views, must remain for further experience to determine. The editors, we may mention, of the *British and Foreign Medical Review*, in their number for October 1837, do not seem disposed to coincide with our views on this point.

## THE CONNEXION OF THE HUMAN PLACENTA AND UTERUS

SHOWN WITHOUT THE AID OF INJECTION.

*To the Editor of the Medical Gazette.*

SIR,

ON the 16th of June, 1839, a gentleman very kindly sent me the uterus of a female, who had died of diseased heart fourteen days after the expulsion of a seven months' fœtus. The uterus measured externally, from the margin of the fundus to the margin of the anterior lip, five inches, and its greatest breadth was three inches. The os uteri was of a dark purple colour, with a granular and somewhat shreddy surface; but it was not fissured.

The internal surface of the uterus presented a granular appearance, from particles of adherent plastic lymph. A portion of the placenta, about half an

inch in thickness at the thickest part, adhered to the anterior part of the body and fundus of the uterus. The free surface of the placenta was granulated and very irregular, with many prominences and depressions. The structure of the placenta was throughout free from any appearance of decay, and perfectly healthy. On cutting perpendicularly through the uterus and placenta, several of the uterine veins were seen to contain tubular concretions of plastic lymph, not adherent to the walls of the vessels, and having both their surfaces besmeared with blood. One remarkably distinct concretion of this kind was seen projecting from the surface of the incision in the fundus. Similar tubular concretions were observed in the oblique vessels passing between the uterus and placenta, quite as beautifully displayed as in William Hunter's preparations now deposited at Glasgow, where they are injected with wax. These, however, were less exactly tubular, and of a less firm consistence, than what were seen in the uterine vessels. Other concretions of plastic lymph within vessels were observed in the substance of the remnant of the placenta. They were the same in their nature, but less distinctly tubular.

On cutting into a dark puckered spot in the left ovary, a corpus luteum was discovered, having a fleshy disc, and a firm white substance in the centre.

The preparation is in my possession.

Your obedient servant,

WILLIAM CUMIN, M.D.

Regius Professor of Midwifery.

Glasgow, Oct. 2, 1839.

## THE VENEREAL POISONS.

*To the Editor of the Medical Gazette.*

SIR,

As my friend, Mr. Skey, in making honourable mention of me in his lectures on venereal diseases, or, as he would exclusively term them, the venereal disease, has indulged his own feelings of kindness and candour rather than my particular request that he would not introduce my name, I am desirous through the same medium of your journal, of stating that my own deductions on the subject of venereal poisons are not to be supposed identified with those

of the very able lecturer. I admit that his bias towards the latest fashion of hypothesis is very moderate, considering the weight of contemporary authority on his side. I cannot, however, but express my own unequivocal dissent from the supposition that all forms of venereal disease are convertible maladies, dependent merely on the constitution of the patient. Some of them, indeed, as the ulcerative phagedæna, and its multiform brood of local affections, the elevated ulcer, &c., may be, and occasionally are, of spontaneous or constitutional origin, as well as contagious; but they are not convertible, as might be inferred from Mr. Skey's own testimony, that the elevated ulcer is not succeeded by secondary disease; whereas the secondary forms of the phagedænic ulcer comprise nine-tenths of the cachectic cases condemned to our foul wards. Every additional day to twenty years of minute observation of venereal maladies, adds to my conviction that there is a plurality of poisons. Of one, the indurated chancre, the lues of Hunter, or, in other words, the scaly venereal disease of Carmichael, is a uniform and individual product. I must further withhold my assent to the position that the question of origin is not practical, for it cannot but be obvious that moral suffering of the gravest character may be inflicted on the already sufficient amount of physical ills by such vagueness of opinion.

Never did truth, even in the uncertainties of medicine, encounter such disastrous adventure as in the whole history of syphilis, from the gratuitous supposition of its transatlantic origin to the modern discovery of its non-existence. To increase the natural difficulties of a subject so extensive in its many relations and resemblances, while some have jumped to the conclusion that there is no specific pox, others contribute to the thickening of the confusion, by supposing progressive alterations and modifications by age, by hybridization with scrofula and scurvy, and lastly, combinations with mercury—all, however, equally indeterminate and anomalous, and all peculiar to this species alone of contagious disease.

To escape, however, at once from this conjectural region, in which

—“Chaos umpire sits,  
And by decision more embroils the fray,”

there seems to me this at least of practi-

cal consolation, that the very language of the confusionists has a gradual but well-marked tendency to fix the peculiar and striking characteristics of the more important venereal diseases. Descriptions of the ulcerative phagedæna, with its peninsula of new skin, the fungous or elevated ulcer, and the marbly hard chancre, are constantly reiterated by those who are the advocates of identity and uniformity. Le Rochefoucault says, it is with love as with ghosts, all the world talks of them, but no one sees them. The converse would seem to happen in venereal maladies, for every one professes to recognise their several lineaments, but denies their separate existence.

On opening, a few days since, the Atlas of Rayer, I observed in juxtaposition the three most important local venereal affections, viz. the phagedænic ulcer, the fungoid or elevated ulcer, and the Hunterian chancre. Twelve years since I communicated some general points of distinction of these three forms to the Medical and Chirurgical Society of London. I have no doubt that the coincidence in Rayer is the simple concurrence of facts, that may be obvious to all who are not blinded by prejudice.

Mr. Travers, however, among others, assures us that "the signs of distinction are becoming obscure, and the bases of them will eventually, he would add, soon be forgotten;" and, moreover, that the Hunterian chancre is nearly obsolete. Now, after all the critical rheum voided on John Hunter, the most faithful and most candid chronicler of his own perplexities and errors, I shall scarce be denied the occasion of expressing my own reverential gratitude for that light which he first brought out of darkness. His very doubts appear to me, even now, better calculated to elucidate venereal diseases, than the assumed certainties of his modern antagonists. He at least led the way through an unbeaten waste, with zeal, patience, and great personal hazard, and if he did not wholly unravel the many mazes of difficulty, he only failed where many more of younger times are still foiled; and lastly, in return for opinions "which," he said, "I have proved so long as to reduce them to conviction," let it be graciously if not gratefully recorded, that, instead of his sagacious account of syphilis becoming

obsolete, after the successive testimonies of Abernethy, Pearson, Carmichael, Evans, and others, to the distinct existence of a Hunterian venereal disease, the latest and very able commentator on his works, Mr. Babington, has justly pronounced his opinion that, in the most essential characteristic of the peculiar induration of chancre, the original description scarcely admits of amendment in its verbal accuracy. May I be allowed to subjoin my own almost superfluous testimony to the existence of the Hunterian venereal disease, or scaly venereal disease of Carmichael, and in the majority of cases of which mercury will still be found always advisable, and often indispensable. To this remedy the malady is in all its forms, and in all textures, so uniformly and readily amenable, that the comparative proportion seen in hospital practice is very small.—I am, sir,

Your obedient servant,

RICHARD WELBANK.

Chancery Lane, Sept. 28, 1839.

#### CONTRIBUTIONS TO DESCRIPTIVE ANATOMY.

By ROBERT KNOX, M.D.

[For the London Medical Gazette.]

---

#### *The Pancreas.*

A VERY general opinion prevails, in this country at least, that the descriptive anatomy of the human organs has been carried to the highest degree of perfection of which the subject is capable. This opinion is unquestionably true in respect to by far the greater number of human organs; still I have always thought that there are some whose anatomy might at least be much improved, and I have selected the pancreas as an organ whose description modern anatomists have not given with all the accuracy desirable in such matters: I say modern anatomists, for it seems to me that descriptive anatomy, although somewhat verbose and surcharged with irrelevant digressions, was of a superior cast in the times of Santorini, Morgagni, Albinus, and Haller, to what it is in the present day: should any critic, therefore, endeavour to shew that most of the facts about to be mentioned might be collected toge-

ther by an industrious student, as they at present lie scattered through the writings of those great men, my reply is, that this is certainly probable; and if my dissections confirm their writings (too much neglected no doubt in the present day), and if the facts themselves are of importance, then I hope it may be admitted that the sooner such descriptions become parts of the text of modern compilations the better.

1. OF THE PANCREAS, from *παν κρεας*, *all flesh*\*. Its general shape and position in the body described from an adult female of middle age.

In its general shape, resembling a hammer with the handle much curved or bent; it is placed in the abdominal cavity, exterior to the peritoneum, and behind the stomach: the larger end, which I shall call "duodenal," is in close contact with the concave side of the duodenum; the smaller or splenic end approaches to within about half an inch or even less of the spleen. The whole organ may be divided into two parts, for the sake of description, viz. a vertical portion and a horizontal portion; the vertical, which is also the shorter and smaller portion, being placed across the other, though intimately united with it, and in a great measure embraced by the duodenum, to whose muscular tunic it closely adheres: the longitudinal portion is much the longer part of the pancreas; it extends from the duodenum, behind the vertical portion, quite across the spine, until it approaches the spleen. This portion lies nearly flat across the spine, and is therefore naturally much curved; its concavity will generally be found to correspond to the anterior surface of a part of the 1st and 2d lumbar vertebræ, and of their connecting fibro-cartilage. The whole anterior surface, which looks almost directly forwards, is covered by the superior layer of the transverse mesocolon; the posterior surface rests upon the suprarenal capsule of the left side and kidney, a small portion of the aorta, and of the last turn of the duodenum, a portion of the splenic artery and splenic vein, and of the superior mesenteric vein, the commence-

ment of the vena portæ; it also lies, in part, on the anterior surface of the middle division of the duodenum, and of the vena cava abdominalis. To all these parts it is connected by cellular substance, varying in density at different points.

The inferior layer of the transverse mesocolon can scarcely be said to invest any part of the posterior surface; the pancreas, however, ultimately rests on the vertebral column. Besides the anterior layer of the transverse mesocolon which covers its anterior surface, the greater part of that part of the pancreas which lies on the left side is concealed by the body of the stomach approaching the cardiac end of the stomach when this viscus is left in its natural position, whilst the duodenal or large end of the pancreas is concealed by the pylorus and pyloric end of the stomach; the intermediate portion, that which lies on the vertebral column, is concealed by the smaller omentum, and may be seen directly on its being cut through. In respect to the margins of the pancreas, it will be found that the upper margin scarcely dips backwards, but that the lower margin looks forward exactly in the middle plane of the body, in consequence of its being supported by the last turn of the duodenum; but if the duodenum be empty, then the inferior margin of the pancreas can scarcely be said to look directly forwards at all, but rather directly downwards.

In respect to these margins: proceeding from the right to the left side, we find that the extreme left, which is slightly notched, but not much narrower than the other parts of the pancreas, approaches to within a quarter of an inch of the concave edge of the spleen, connected to it and to the posterior surface of the cardiac end of the stomach by the peritoneum. The splenic artery turns behind this upper margin for about an inch and a half, but for the other three inches of its course it lies above the margin of the pancreas, between it and the stomach, and rather in front of the pancreas than otherwise; the splenic vein throughout nearly its whole course lies behind the pancreas and inferior to the artery, but even this vessel when within an inch of the left extremity of the pancreas, ascends somewhat above it in order to reach the spleen. About the middle of the pancreas and where it

\* Butchers in this country call it the kernel behind the liver; they have no name for it, and they do not know its use. Indeed, as was to be expected, I have found such persons altogether ignorant of the use of most parts of animal bodies.

lies in front of the vertebral column, the cœliac axis will be found directly behind it; the commencement also of the hepatic artery will be seen here, but this vessel soon gets above the superior margin of the pancreas, and ascends towards the liver, crossing the vena portæ in its course from the left towards the right side. The vena portæ ascends from behind the pancreas towards its upper margin, two inches from the termination of the gland on the right side. In respect to the lower margin of the pancreas, we find that it is supported in the centre by the last turn of the duodenum, while to the right side we find the superior mesenteric artery coming out from below the inferior margin, at the distance of three inches from the concave side of the duodenum: the principal branch of the superior mesenteric vein may be seen a little to the right side of the artery.

Thus the commencement of the vena portæ lies behind the pancreas, as near as may be, two inches and a half from the duodenal end. The total length of the gland without being stretched is somewhat more than nine inches; narrowest part of which is, to the right of the spine, one inch; broadest part of the horizontal portion, which is to the left side of the column, one inch and three quarters; vertical portion measured in its longest axis nearly three inches: this part of the gland, which lies in front of the ductus communis choled. is in the closest union with the vertical portion of the duodenum on its second turn: it is somewhat in front of the intestine, and on its concave side, and is in immediate contact with the muscular fibres, to which it adheres by means of a close cellular substance so that on removing the gland from this part of the intestine the muscular tissue is immediately exposed. This intimate union between the gland and duodenum commences three inches from the pylorus, and continues for three more. Very generally the duodenal part of the gland partially envelops a larger division of the inferior mesenteric vein, by sending a process to the extent of nearly three-fourths of an inch behind the mesenteric vessels, in this way the gland forms an incomplete sheath for these vessels.

The gland and duodenum being now removed for a more careful examination of its form, the following particulars

were observed, and although anticipating somewhat, they will be found applicable to most specimens of the adult pancreas. The pancreas has no special capsule, but it is invested by a layer of cellular tissue, which plunges into it at almost all points: it is smooth externally, and by prolonging itself into the interior of the gland, serves to support and partially insulate the smaller lobes and lobules of which the pancreas is ultimately composed. By cautious dissection, commenced on its posterior surface, these lobes may be so separated from each other as to allow of the main duct (duct of Wharling) being exposed without necessarily cutting into the substance of the lobes themselves. From these lobes and their lobules may be seen at this stage of the dissection numerous smaller ducts proceeding to join the main duct, at various, but generally at right angles, or at somewhat acute angles, the angle being turned towards the splenic end of the pancreas. There are, however, as we shall afterwards find, others which join at an opposite angle; that is, running from the duodenal towards the splenic end.

In respect to the form of the pancreas, it is extremely difficult to describe by words the exact course it follows: the accompanying figures, and their explanations, will, I apprehend, be more useful to the reader than any description: it may be observed, however, that the horizontal portion of the gland (the pancreas of Winslow), commencing by a somewhat pointed, notched, and irregular extremity, near the spleen, soon acquires its full breadth; this is about opposite to the spinal column; the gland soon after this contracts, becomes rounded, is curiously twisted upon itself, and here, to the right of the spine, will be found the narrowest part of the gland. A little further on to the right side it joins the vertical portion, (smaller pancreas of Winslow) which, as it were, conceals it, sending a process towards its upper margin and anterior surface, and another behind the mesenteric vein towards its lower edge and posterior surface. This vertical portion, or smaller pancreas of Winslow, is also very singularly twisted upon itself; its extent and connexions with the duodenum have been already related. In what respect, then, these portions of the pancreas may be considered as separate glands, remains to

be considered; this question will come in more naturally after the examination of the duct or ducts of the gland.

I come next to speak of the duct or ducts of the pancreas. The text of M. Jules Cloquet's folio work contains a very brief history of the pancreas, and describes it as usually having a single duct. On referring, however, to the very beautiful engraving which accompanies that work, we find represented a pancreas which not only has *two ducts*, entering the duodenum *separately*, but which moreover represents these ducts as uniting with each other by their radicles or branches. As this plate of M. Jules Cloquet figures in an elementary work, the student might be led to suppose the distribution of the ducts here represented to be the normal one. The figure, however, has been merely copied from Santorini, and exhibits an arrangement which cannot be considered the normal or regular one; it is to be regretted, therefore, that M. Cloquet did not cause a few dissections of the pancreas to be made, and thus the normal arrangement would have been brought before the

student. It occurred to me, that the best, though perhaps not the only way to supply this deficiency, in our elementary anatomical works, was to examine a certain number of specimens with care, and draw from the result some general inference or average.

Another mode of deciding this question will, undoubtedly, occur to the reader, viz. a reference to the best authorities—to the writings, in short, of the anatomists whence modern compilations have been chiefly drawn. I have preferred the former method as being more congenial with my usual pursuits, but have not neglected the latter; such authorities as De Graaf's, or Santorini's, could not, with propriety, be overlooked. With a view of preventing any bias in the mind of the reader in favour of the conclusions I may ultimately draw from the following dissections and references, I had better enumerate them in the order in which they occurred. The dissections were made from a series of specimens taken from the practical rooms, but not selected; they all occurred in a few weeks.

FIG. 1.

Explanation of Fig. 1.

d.d. The duodenum.

p.p. The pancreas.

w.w.w. The duct of Wirsung or long duct, entering the duodenum separately  $3\frac{1}{2}$  inches from the pylorus.

s.s. Small duct of the pancreas, entering the duodenum along with the ductus communis choledochus, 5 inches below the pylorus.

d.c. Common biliary duct or duct communis choledochus.

The above figure is a mere sketch of the *first pancreas dissected with a view to ascertain the normal arrangement of the ducts*; and by a curious coincidence, it presented a variety scarcely described by any author: the organ happened to be the subject of the demonstration to the class; it belonged to an adult female beyond the middle age; the *shorter*

duct nearly equalled the longer in calibre: it collected branches from nearly the whole of the vertical or duodenal section of the pancreas, but not *exclusively so*. Its union with the common biliary duct was so intimate that they seemed to have but a common orifice into the duodenum. The ducts seemed not to communicate by anastomosis with

each other. Thus, the first pancreas examined presented the rarest variety, I imagine, which has occurred to any anatomist. It is unnecessary to point this out at greater length to the anatomical reader. I shall here take the liberty of cautioning the young anatomist, that the ducts, being so very varied

in their arrangement, require to be injected and dissected with great care. In the present, my assistant, an excellent and careful dissector, did not observe the duct at all, although, previous to my seeing the gland, he had dissected the larger duct for demonstration to my class.

FIG. 2.

Explanation of Fig. 2.

*d.d.* The duodenum.

*p.p.* The pancreas.

*w.w.* The duct of Wirsung, or long duct.

*s.s.* Small duct of the pancreas.

*b.* Communicating branches between the small and large ducts.

*e.* Termination of the small duct in the duodenum, about  $1\frac{3}{4}$  inches above the termination of

*f.* The longer duct, opening into duodenum along with the common biliary ducts.

*v.* Marks a considerable branch running in an opposite direction to most of the different branches; it is worthy of notice that this branch joins the main one

near to a part where, in some specimens, the main duct divides into two branches. At a hasty glance the variety here offered might seem precisely that described by Santorini, copied by M. J. Cloquet as the usual structure, and by many others, but it is not exactly so, as will be shewn presently; as it is that, however, which approaches it in all its essential particulars, I shall, at this stage of the memoir, first describe the specimen from which fig. 2 was taken, and next offer a few remarks respecting the engravings and text of Santorini.

I have already mentioned that the pancreas I now describe was not *selected*, but simply occurred in the dissecting rooms *next after* the preceding one. It was of great size, which reminds me how much this gland is known to vary in different individuals, both as to bulk and weight (but not in form, as will afterwards be shewn). In dissecting it the duodenal entrance of the large duct, or that of Wirsung, was first sought for, and through it a warm coloured injection of tallow and vermilion was thrown into its duct, and its branches filled in a direction the opposite of their course. The injected material speedily filled the large duct and all its branches, and a very little force being used it returned into the intestine by an orifice placed about  $1\frac{3}{4}$  inches above; this orifice evi-

dently belonged to another duct, probably resembling, in its course, the duct described by Santorini. By a careful dissection, the parts, as represented in the figure, were finally made out. From the great size of this pancreas, many points in its history, respecting the particular shape of its individual parts—the remarkable twisted portion, where the gland is narrowest—the twisting also of the vertical or duodenal portion, were all remarkably prominent. As this arrangement differs in no very essential particular from the engraving of Santorini, it may seem to some that copying the figure of Santorini in this place is supererogatory. I hope, however, to satisfy the careful reader that this is not the case.

FIG. 3.

*Copied from the celebrated work of Santorini.*

- |   |  |

| 2. Middle part of the same gland.       | denum.                                   |
| 3. Tail of the pancreas.                | 7. Duct. com. chol.                      |
| 4, 4, 4. Prolongation named "small pan- | 8. Accessory pancreatic canal.           |
| creas" by some authors.                 | 9. Its termination in the duodenum.      |
| 5, 5. Pancreatic canal of Wirsung.      |  |

Having placed both figures before the reader, I shall now take the liberty of making a few remarks respecting the text. The whole of the text does not strictly belong to Santorini, but partly to the editor who published the work after Santorini's death.

The work of Santorini contains three very beautiful engravings, having reference to the distribution of the pancreatic ducts, but not exclusively. As in all these the same arrangement of the ducts is represented, an inference arises naturally enough in the mind of the reader—viz. that they were all probably copied from the same dissection. But by the text we also discover that Santorini, or his editor, or both, I rather think, considered the above arrangement as the normal one, and even dwelt on the trivial and unimportant circumstance (unimportant because liable to variety) of the ducts anastomosing with each other in the precise mode in which they are represented in this engraving. Of the "superior or upper duct," as he terms it, he thus speaks—"ut ductum hunc constantissime comperi, ita frequentissime in longiorem influentem aut si lubet effluentem dicere adverti ut alterutro inflato, sicuti etiam habet Graafius, uterque statum attolatur."—P. 15. Although disposed to consider this a common enough variety, it does not seem to me so well entitled to be considered the normal one as Santorini supposed.

But to return; after asserting this arrangement of the pancreatic ducts to be a very constant one, and dwelling on the circumstance, altogether trivial, of the short duct collecting some of the smaller ducts from the vertical portion of the gland, then joining the main duct, from which another short duct again proceeds to enter the duodenum by itself, considerably above the termination of the longer duct and biliary tube, the editor of Santorini proceeds to criticise De Graaf for not having laid sufficient stress on these facts; he accuses De Graaf of not having taken any notice of the short duct in his (De Graaf's) engraving, which is just as if he should find fault with an artist for having omitted that which, on the object before him, had no existence. He also asserts that De Graaf confounded the short or superior duct with the other small branches joining the main duct; but we shall afterwards find that De Graaf simply drew what he saw, and that these conclusions of Santorini's editor are incorrect, inasmuch as it frequently happens that the pancreas has but a single duct, into which none other enters of so superior a size to the others as to merit the name of a *small duct*. Further, this anatomist fancied that the pancreatic ducts had very constantly *two duodenal apertures*; assuredly he was much in error. But the truth is, that De Graaf knew better; he knew all these particulars to be mere varieties,

as I shall endeavour to point out in describing figure 4, which most nearly resembles De Graaf's engraving of the pancreas and its ducts.

A part of this critical history of the engraving of Santorini, and that not the least curious part, is, that both plates have been copied into M. Jules Cloquet's folio work without the smallest reference being made to the arrangement in the descriptive anatomy of the gland, so that the reader is startled by finding that the text and the plates do not accord, the text describing the duct as single; the plates showing it to be double\*.

[To be continued.]

## MEDICAL GAZETTE.

*Saturday, October 12, 1839.*

"Licet omnibus, licet etiam mihi, dignitatem  
*Artis Medicæ* tueri; potestas modo veniendi in  
publicum sit, dicendi periculum non recuso."  
CICERO.

### THE

## MANAGEMENT OF HOSPITALS.

A SHORT time since we gave our readers an account of the general character of the scheme of hospital management, in Paris, as described in the report of the Medical Commission of 1838. It is but right that both sides of the case should be heard; and we will now, therefore, examine the counter report of a special Commission, not composed exclusively of medical men attached to the hospitals, but appointed by the general board of administration, to inquire into the truth of the heavy charges brought against them. We are indebted for our information on this report to our excellent contemporary and

namesake, *La Gazette Médicale de Paris*.

The following statement may afford an idea of the amount of assistance given to the sick and infirm of Paris:—12,000 old and infirm people are admitted into the hospices; 76,000 patients pass annually through the hospitals (giving an average of about 4800 patients a day); 4600 foundlings are placed in a special asylum, 16,000 are maintained in the country, and more than 400 put to apprenticeship. Besides these, 30,000 indigent families receive private assistance. The returns of the Commission of inquiry into the public Charities of this country are not (at least in that part which relates to the hospitals) yet published; but we believe we may say that even allowing for the difference of population, and the fact that, *cæteris paribus*, the greater the population the greater will be the proportion of those requiring relief from public charities—allowing for these things, the number relieved in Paris is very far less than that of those who obtain assistance in London; so that in regard to the quantity of assistance afforded, a voluntary system would in this, as in many other instances, appear decidedly preferable to one dependent on public compulsory contribution. We of course exclude here the consideration of the protection and maintenance of foundlings—of whom there are more thousands publicly supported in Paris than hundreds in London. The strictness of our bastardy laws, effectually, though perhaps sometimes too harshly, restrains the licentiousness which the French system permits, and even encourages, in this respect; and considering how large a proportion of their charitable funds must be expended for this bad end, and what need there appears of pinching economy in their distribution, it is surprising that the administration should not curtail here, to enable themselves to

\* Were I disposed to criticize farther, it would be easy to find room for it here. M. Cloquet has copied Santorini's dissected gland, whereby its true form has not been represented, for the undissected pancreas differs a good deal in its shape from the engraving of Santorini, which M. Jules Cloquet copied. Notwithstanding, therefore, the beauty of the original engraving in Santorini's works, there could scarcely be imagined a more incorrect view of the gland than he has given us.

be liberal towards the more deserving objects of their charity.

But for the *quality* of the assistance afforded to the sick and needy under the English voluntary, and the French compulsory systems—the character and talents of the medical attendants do not form a part of the inquiries of this commission; but we met with an observation a short time since which we shall take this opportunity of introducing to those of our readers who may still believe that the system of *concours* must be the most efficient in securing the services of the best men, and therefore that, in this respect at least, we are far behind our continental neighbours. The remark we allude to was made by M. Magendie, the liberality (to call it by the mildest name) of whose opinions is well known. “This style of teaching” (the sciences at the College of France, he says) “unavoidably requires a particular mode of electing the men who are to fill our chairs. The choice of the profession is not here trusted to the chances of the *concours*, (*aux chances du concours*). It would not be sufficient, in a fortunate contest, to have surpassed some rivals; the whole philosophic world composes the jury\*,” &c. The chances of the *concours*! Why, the very and peculiar merit of the scheme used to be that it excluded chance—yet a French liberal acknowledges it inferior to the plan of electing a man according to his public reputation, the plan which it has been so fashionable of late to revile, and to regard as the bane of the medical schools and hospitals of this country.

We may assume, then, that in regard to the efficiency of the medical attendance upon the poor, our voluntary system is at least not inferior to the involuntary.

With respect to the yet more im-

portant matter of providing food and medicine, we find from this return that the expenses of all the establishments for the relief of the poor, mentioned above, are rather more than 12 millions of francs (nearly 50,000 pounds) a year, about half of which is obtained from their own resources, or endowments, and the rest from a rate paid by the town. The annual amount of the whole rate from which this sum is derived is at most 29 million francs; of which upwards of three million are paid to the treasury, five million for the interest and liquidation of the debt, and about two million in the expenses of collection, &c.; of about 17 million that remain, one-third is allowed to the hospitals, and other similar charitable establishments.

Now when it is considered that each of our royal hospitals possesses and expends an income of about one-fifth less than the whole hospital and other similar public expenditure of Paris, it is scarcely imaginable how, on the one hand, so many cases can be relieved at an expense comparatively so small, or how, on the other, an outlay so large can be disposed of to so comparatively small a number of objects of charity. Nearly 50,000 patients are on the whole relieved each year at each of the great hospitals of this metropolis, while at Paris 76,000 are relieved at the hospitals, and upwards of 30,000 children and old persons are constantly maintained, and 30,000 families occasionally assisted, for about one-fourth more than the annual expenditure of one of our hospitals. Nor let it be imagined that the outlay at our largest endowed hospitals is in any degree more profuse than at those which are chiefly supported by continued voluntary contributions. We know that on the whole the expenditure of all the hospitals in London, is at nearly the same rate, for the number of patients relieved. It is evident, therefore, that there must be on one side,

\* *Leçons sur les Phénomènes Physiques de la Vie*, t. ii. p. 2.

wanton extravagance, or on the other most pinching penury. We shall most easily and most clearly find evidence of the latter in one particular of the calculations presented by this commission.

The previous (medical) commission had particularly pointed out the poverty of the regimen adopted at the Bicêtre and the Salpêtrière, in the division of the old and infirm; and the administration itself acknowledges, in this report, the necessity of insuring them a more substantial supper. Now, say they, calculating the expense at five centimes (one halfpenny) a head, as there are about 8,000 individuals to be fed, there is an expense of 400 francs a day, or £6800 a year. The increase which the physicians solicited being granted, caused, although it was but a slight increase of supply, an addition of £1200 to the annual expense; from all which we learn, in a few words, that the old and infirm can be, and are, supplied with supper at the rate of six-tenths of a penny a head.

After this it need scarcely be said, that, although this last counter-commission denies in strong terms, and on apparently good evidence, the assertions of the medical commission of the destructive effects of the bad and scanty diet allotted to their patients—and although its members contradict or explain away a considerable number of the declarations of the medical men—yet they are far from justifying the present plan of feeding, and acknowledge that the milk is bad, and the bread ill-baked, and that the meat does not “come up to the sample,” and that more green vegetables should be supplied, and that fresh butter ought to be used instead of salt; and some other things of that kind. Little more, perhaps, need be urged; the articles enumerated, and allowed to be bad, constitute probably the whole of the patient’s diet; yet we can-

not but wonder how even *they* can be supplied at the rate of so little more than one halfpenny a head for supper.

There does not appear to be any just cause of blame upon the hospital administration; the charges brought against them by the medical commission, of jobbing and of extravagance, where their own interest was concerned, were probably exaggerated, and for the most part unfounded. No one who looks at the income they have to expend, and the enormous number among whom it is distributed, will have much hesitation in according the French hospital administration great credit for their success, though he may regret that the assistance they afford is of necessity so limited, and dealt out with so close a hand.

In turning from the condition of hospital charity in France to consider its state in our country, one cannot but indulge a deep feeling of national pride. Stand where we may in this metropolis, we are almost in view of some institution founded and maintained by the voluntary gifts of our fellow-countrymen, in which assistance is dealt out to the needy with open and liberal hands, and where the poor are treated less as suppliants than as just claimants for relief. And why, if this great and good end be attained—why should we be so anxious to ferret out some corner in which there may be a little jobbing going on; or, at least, why should we make it the chief object of our regard, or think that a little flaw, which almost needs a microscope to exaggerate it into visible dimensions, mars all the beauty of the great edifice? Let it be granted that, in some cases, private interest is served; that this hospital is maintained by the friends and supporters of its physician or surgeon; that in that there is a governor who subscribed only that he might assist his

own trade, or serve his friend's interest; that another is, in some measure, upheld to gratify this or that great man: what are all these when compared with this great end—that thousands of the poor are assisted in their hour of need, relieved with a liberal hand, treated with kindness, guarded by talent, watched over with assiduity, and preserved from all the accumulative evils of diseased poverty. There is not, we are convinced, in the land, an object that an Englishman may justly regard with more complacency than our hospital establishments; nor is there a subject in which the political economist may find more stringent evidence in favour of a system of voluntary relief, than in the comparison which may be instituted between our hospital and our poor-law charity, or between the systems of hospital relief in France and England.

To our mind there can scarcely be a stronger case than is here presented; nor are the causes of the difference obscure. When a body of men have to expend the money which others have been *forced* to give, and when they know that the only feeling with which they are watched is one of anxiety lest that which was unwillingly entrusted to them should be carelessly or extravagantly expended, no wonder if they endeavour to acquire the only reputation that is possible—a reputation for economy; no wonder if, hearing on the one hand the groans of the taxed, who are strong, and, on the other, those of the afflicted who are weak, they pay attention only to the former. But it is far different when men expend that which is voluntarily given to them to dispose of; for they then only fulfil the wishes of the giver, when they bestow the greatest possible happiness upon the greatest possible number of receivers.

## CLINICAL LECTURES

ON

## OPHTHALMIA.

BY M. VELPEAU.

*Reported for this Journal, by*

J. HENRY BENNET, B.L. & B.S.

Sorbon.

### SEQUELE AND COMPLICATIONS OF KERATITIS.

*Description of different kinds of opacity of the cornea.—Treatment.—Dieffenbach's operation.—Iritis.—Historical detail regarding the disease, first described by the German and English surgeons.*

ULCERATION of the cornea is always followed by a certain degree of opacity of that membrane. This opacity may be compared to the cicatrix which follows the ulceration of other membranes, and as it generally more or less impairs the visual functions, it has attracted much attention. Authors have described many kinds of opacity, but they may be all comprised in three species: the *nebula*, in which the opacity occupies only the superficial lamellæ of the cornea; *albugo*, in which the middle layers are also affected; and lastly, *leucoma*, in which the entire thickness of the cornea has become opaque. I may also mention another species of opacity which has been but little noticed by authors, probably because it offers no impediment to sight, the *senile zone or ring*.

The *nebula* consists in a slight opacity of the superficial lamellæ of the cornea. The word itself indicates the nature of the opacity; it may be compared to a slight mist or cloud, obscuring, but not destroying the transparency of the membrane. This lesion is often confounded with the *nepheleon*, or superficial ulcer of the cornea, the *achlys* of Galen, which, as you will remember, rests on a slight *nebula*. We may thus account for Scarpa's asserting that a *nebula* is always accompanied by slight vascularization of the conjunctiva, my own experience enabling me to say, that when the *nebula* is unaccompanied by ulceration of the cornea, the vascular appearance noted by Scarpa does not exist.

An *albugo* is an opacity of sufficient density to intercept the passage of light through that part of the cornea on which it is situated. The principal distinction between *albugo* and *leucoma* is, that *albugo* does not occupy the entire thickness of the membrane. It may be situated in any part of the cornea, is of a milky yellowish colour, and is met with as a se-

quela of intense chronic keratitis, of abscess, or of ulceration of the cornea.

*Leucoma*, generally the result of a cicatrix, of lengthened suppuration, or of intense inflammation, is not merely characterized by opacity of the entire membrane, but also by other modifications which the texture of that membrane undergoes. It becomes hard, callous, thickened, and its vitality is diminished.

The *senile zone* is a circular, opaque ring, natural in old people, occupying that part of the cornea which is immediately adjoining to the sclerótica. It cannot be attributed, properly speaking, to disease of the cornea, the structure of that membrane not being altered, nor its thickness increased; and as the functions of vision are not impaired, little or no attention is, in most instances, paid to its presence. This form of opacity, extremely common in old age, is occasionally met with in all other periods of life. It generally commences on the superior portion of the cornea, then invades the lower hemisphere, and it is only as the patient advances in years that the two arcs join laterally. With old people, the opaque ring is always separated from the sclerótica by a small interval of transparent tissue: but this is not constantly the case in younger persons.

*Treatment.*—The treatment of the various species of opacity of the cornea has been much studied by surgeons; nor need we be surprised, when we consider that the slightest nebula situated opposite the cornea, must, more or less, disorder the visual functions. The non-medical public entertain singular notions respecting the nature and the treatment of these lesions: nothing, indeed, is more common than to hear patients affected with opacity of the cornea complain of having a membrane over the eye, which they wish to be taken off. However ridiculous the idea may appear, we shall see presently that such an operation has not only been proposed, but even put into execution by some practitioners. You must remember that the public in general know nothing whatever about medicine, and that all the absurd ideas respecting the treatment of disease which are current in the world, have originated with medical men. Even those remedies which we call “old women’s remedies” have been at one time employed by the profession; thus you will find that cow-dung, which they advise in inflammatory humours, is greatly extolled by Avicenna.

In most instances, opacities of the cornea are indelible; there is nothing to be done. Indeed the attempts which are made to remove an albugo, or a leucoma,

often increase the gravity of the lesion. When, however, the opacity is merely a nebula, and one or two of the superficial lamellæ of the cornea only are affected, there is some chance of being able either entirely to remove it, or at least to increase the transparency of the membrane. The white matter, combined with the tissue of the cornea, instead of the transparent fluid which it generally contains, and the remedies which are employed being applied to the surface of the affected membrane, may penetrate and modify the nature of the effused matter. Among the therapeutic agents which are the most frequently resorted to with this view, are the various collyria employed in the treatment of ulcers of the cornea; as also the sulphate of zinc, calomel in powder, the solid nitrate of silver, Sydenham’s laudanum, &c.

Some of these remedies, such as laudanum and the lunar caustic, enjoy greater reputation than others. They certainly may sometimes be used with success to dispel slight nebulæ, when there is no inflammation; but if they are employed whilst the inflammation of the cornea still exists, they nearly always occasion a renewal of the ophthalmia. The nitrate of silver, used as a caustic, was much praised, a few years back, by M. Lallemand, who advises the opacity to be slightly cauterized five or six times in the course of the month. I think, however, he must have mistaken for a nebula the superficial ulcer of the cornea or nepheleon, against which canterization generally proves successful. I have several times tried the nitrate of silver in the treatment of nebulæ, and constantly seen the malady exasperated.

In the last century, a surgeon, named Gouan, pretended he could cure nearly every species of opacity of the cornea with a liquid, the composition of which he kept secret. The secret was bought up, and this marvellous remedy turned out to be merely oil of walnuts. To support his assertions respecting its efficacy, he appealed to the authority of Linnæus, as also to the customs of the inhabitants of the Pyrenees, who had employed it against opacities of the cornea from time immemorial. The remedy had been long forgotten, when, a short time since, it was again brought forward by M. Carron-du-Villards, who makes use, however, of cod-oil, and not of walnut-oil. I will not take upon me to decide which is to be preferred; yet I must say it appears to me, that, if one is an efficacious remedy, the other cannot be much inferior. With regard to the therapeutic properties of the oil, I do not believe that it can cure any other form of opacity than the nebula.

Some surgeons have advised that the opacity, when it does not occupy the entire thickness of the membrane, be excised, or gradually worn away by scraping; but there are no facts before the profession to prove that such an operation has ever been successfully performed. Whether the opacity be worn away or excised, there must evidently remain an epicauma ulcer on the surface of the cornea, which, on cicatrizing, would itself give rise to opacity. The only case in which scraping or excision could be excused, is that in which a plastic ulcer leaves behind it, on the cornea, some coagulated lymph; and even then I would not myself resort to such a measure.

According to Mr. Jacob, of Dublin, the use of the nitrate of silver in the treatment of ulcers of the cornea is often followed by a blue coloration of the cicatrix; but the cases he brings forward do not, in my opinion, satisfactorily prove the fact. I have myself employed the nitrate of silver as a solution, as an ointment, or alone, in many hundred cases, without ever observing such a coloration. I know not, therefore, what to say, and can only explain the fact by supposing that the nitrate of silver must act differently in England to what it does in France.

The excision of the plexus of varicose vessels which often corresponds to the affected part of the cornea, has been much lauded by some surgeons, and especially by Scarpa, whilst others, on the contrary, look upon the operation as nearly useless. This diversity of opinion may, however, easily be explained. When the opacity is kept up by the deep-seated or sclerotic vessels, excision is useless; but when it is the conjunctival vessels only that are morbidly developed, their section may produce, as Scarpa says, extraordinary results. This we have already seen to be the case when excision is performed in chronic keratitis, and in ulcers of the cornea.

As a last resource, when an albugo or a leucoma exists which entirely intercepts the passage of light into the eye, a singular remedy has been proposed—the excision of the affected portion of the cornea, and the subsequent union of the lips of the wound by suture, or the substitution of the cornea of some animal. M. Dieffenbach, a surgeon in every respect worthy of confidence, told me that he had successfully performed the operation on a young girl seven years old. Having fixed the cornea with a small tenaculum, he excised at once the affected portion. M. Dieffenbach also said that he thought an opaque cornea might be replaced by that of an animal. This operation was formerly proposed by Pellier, who even says that

he had successfully performed it; but I do not place much reliance on his statement, for he was a specialist, and those gentlemen have generally something more in view than the interest of science. The operation appears to me, I must confess, perfectly absurd; indeed, I am at a loss to conceive how it could originate in a properly organised mind.

#### *Iritis.*

It is believed by many that iritis is a disease known only to modern writers; but if we peruse the treatises on ophthalmology which are anterior to the present century, we shall find that the existence of inflammation of the iris has always been recognised, although it is only since the commencement of the nineteenth century that it has been considered apart from the other inflammatory affections of the eye. Some authors had, it is true, done more than merely mention the existence of iritis, but as they confounded it with various diseases of the eye, the descriptions they give are vague and unsatisfactory. The Germans and the English were the first to separate iritis from all other ocular affections, and to make it a distinct disease; but in doing so they have gone rather too far, their views being in my opinion too exclusive. Iritis exists, most certainly, as a distinct affection, and ought to be described as such, but, owing to the anatomical situation of the iris, it is hardly possible that it should be inflamed without the inflammation extending more or less to the adjoining tissues. It is, therefore, evidently necessary, in describing the malady, to take into consideration the various complications that may occur. At a future period we may be able to isolate completely iritis from all other inflammatory affections, but in the present state of science it is quite impossible to do so. Those, indeed, who have attempted it have invariably confounded, under the name of iritis, several inflammatory diseases which cannot in reality be referred to the iris.

Although it be to the German and to the English surgeons that we owe the first accurate description of iritis, you must not suppose that the affection was previously unknown to French writers. Maitre-Jean speaks of it in very plain terms; Deshaies-Gendron describes it in treating of the iris; Janin published a case of iritis in his work on ophthalmology, and several other authors have spoken more or less briefly on the subject. Beer is, however, the first who carefully described iritis. Two years later Schmidt published an interesting memoir on the disease in question, and nearly about the same time Ware and Saunders, in England, and at a

later period, Mr. Travers made known the results of their researches. During the first twenty years of the present century France did but little towards the advancement of this branch of ophthalmology, but in 1820 M. Guillé (Diet. des Sciences Médic.) and M. Müller (Bibli. ophthal.) entered the arena, and in 1823, M. Gillet de Grammont gave in his thesis as good a description of the disease as can be met with in the works of any foreign author. Since then many surgeons have written on the subject.

From this slight historical sketch, it appears that iritis has long been known to French writers, who, however, confounded it with various inflammatory affections of the eye, but that it is to foreigners that is due the credit of having first carefully studied the malady, and separated it from other diseases. It yet remains to be proved whether, by passing from one extreme to the other, the latter have not to a certain extent impeded the progress of science.

On looking over the different statistical accounts of diseases of the eye that have been published, we are at first surprised to find that iritis is by no means as common with some practitioners as with others. The difference of opinion which still exists respecting this malady will, however, at once account for the circumstance. It is, indeed, extremely difficult to limit iritis, as many of the symptoms which are referred to it by some writers are attributed by others to inflammation of the choroid membrane, of the retina of the vitreous humour, or of the capsule of the crystalline lens.

I do not flatter myself that I shall be able completely to solve this pathological question, but as I have seen a great deal of the disease, and have attentively studied its characteristic symptoms, as also those of the inflammatory affections by which it is generally accompanied, the description which I am about to give may throw some additional light on the subject, and will, I think, give you more correct knowledge of the malady than can be gathered from our classical works on ophthalmology. There is, however, still much to be done before we can be said to have attained a perfect knowledge of this department of ocular pathology, to which I cannot too strongly recommend practitioners to direct their attention.

Iritis may, like all other inflammatory affections, be either acute or chronic. We will first study the acute form of the disease.

## MEDICAL SCHOOLS

AT CAIRO, ATHENS, AND CONSTANTINOPLE.

THE medical school of Egypt, which for some years has been located at *Abou-Zabel*, is now removed to *Esbekie*, in the immediate vicinity of Cairo; the former being too remote from the capital, to enable the professors, from their necessary duties in private practice, to do full justice to the institution. The school makes part of a large and well arranged military hospital, beautifully and pleasantly situated on the western bank of the Nile, in the suburbs of Cairo. This hospital contained thirteen hundred patients when we visited it. The immediate connection of the medical school with this large hospital, together making one great edifice, is in my opinion an admirable arrangement for the benefit of the pupils, and well deserving of imitation in other and more enlightened countries. The lecture rooms of the professors are all exceedingly well arranged, and the amphitheatre for anatomy is particularly well constructed, with abundance of light from a cupola on the top. A large and well arranged pharmacy, with specimens of every kind of domestic and foreign drug, while it abundantly supplies medicines to the wants of the hospital, serves as a means of instructing the students. A large laboratory is connected with it, in which the new chemicals, such as alkaloids, and others, are prepared, to answer the demands of the physicians, and at the same time extend information to the pupils, by making them acquainted with chemical pharmacy.

The number of pupils attending the lectures at the time of our visit was two hundred and sixty. They are not only attendants upon the lectures of the professors, but residents in the hospital, in order to observe the treatment of the patients, and to become familiar with the almost endless forms and features of disease.

They are all educated at the public expense, have their quarters in the hospital, where they eat and sleep, and are obedient to a regular military and medical discipline, and rank as *sous aides*, in the surgical staff of the army. Here they are compelled to remain from three to four years in the constant pursuit of their studies, and in the regular observance of disease, at all times obedient to the call of their superiors, and ready to administer to the wants of the patients.

The beautiful order and methodical arrangements, as well as neatness, in every part of this establishment, surprised

and delighted me. It unites the activity of the French, with the cleanliness and good system of the German hospitals, and therefore may be said to have the excellence of both.

The anatomical museum is very respectable, and will serve as the nucleus of a good collection. It consists mostly of bones, casts, and wax models, with the excellent tributary aids, of parts, and the whole subject, of the ingenious invention of Dr. Anzoux. From the expense of alcohol, and the great waste, owing to the excessive heat and dryness of the climate of Egypt, few or no specimens of morbid parts can be preserved as wet preparations. They are compelled to resort to drawings and wax models, to perpetuate their similitude.

The apparatus for the illustration of the physical sciences is neat, and sufficiently ample.

The Civil Hospital is situated in the city of Cairo, and is located in a spacious building, but recently one of the palaces of Mahomet Ali. It is placed very favourably for good air, near the principal square of this very curious and truly oriental city. It is an admirable transfer of the noble and superfluous domain of a single individual to humane and charitable purposes, to the wants, necessities, and the afflictions of the poor and the diseased. As the medical officers informed me, it had only been established about one year, and was but a beginning of an asylum, and a home, for the suffering and the sick.

It contained between two and three hundred patients, besides apartments especially appropriated for a lying-in establishment. Although there is a male and female department in the same building, there is the peculiar eastern vigilance, and harem-like care, that the females shall not even be seen by the male patients. On no pretence, whatever, is any male admitted into the female part of the hospital unless he be a professional man, and then he must accompany a medical officer of the establishment, who only has authority to introduce him.

Connected with this maternité, is a school for the education of young women, to fit them properly to be accoucheuses or sages-femmes. It has a well organised class of young females from the age of fifteen to twenty, under the care of a French professor, aided by a young Arab, whose acquaintance with the French language enabled the pupils to comprehend readily the lessons of the principal. The class consisted, on the day of our visit, of sixteen. They were dressed as Europeans, were very neat and respectable in their appearance, and exhibited various tints, and

shades of colour, from the tawny Arab, to the jet black Nubian and Abyssinian.

They were all assembled in the class, at their lessons, when we entered, and were receiving instruction from the professor. Their note-books were in Arabic and French. I was requested to test the practical knowledge of one of them on the mannikin. One, the most convenient, and as black as ebony, was requested to come forward. Different questions in French were put through the young Egyptian, and on the machines the pupil proved by her manipulations with the fœtus, that she not only comprehended perfectly the question, but that she understood well the subject.

When their knowledge is thought sufficient, they are permitted to exercise the art upon the patients of the institution. In this way, after a residence of some time in the hospital, subjected to regular discipline and instruction, they become very competent practitioners of this branch of the profession. They informed me that all of them were educated at the expense of the Pasha, and that his object was to place them in the harems, and thereby dispense with male obstetricians; that Mahomet Ali, from time to time, was in the practice of purchasing young females at the slave market at Cairo, and placing them in the maternité for instruction. In this way he kept up a constant supply for the wants of the different harems of his family and favourites.

This establishment is undoubtedly founded upon the liberal and humane plans of the French, who annually educate, and send forth a large number of well instructed and competent young women, not only in every direction through their own provinces, but into other countries. It is to be hoped, that in Egypt, a more enlarged and liberal view will be taken of this system, and ere long that its salutary and benign influence will be extended far beyond the gardens and walls of the harems; and that the almost countless poor may receive something in return for what they labour so hard to support.

Every facility seemed to be afforded in this obstetric school, in preparations, apparatus and instruments, as well as the living subject, to make the pupils competent and useful practitioners.

An attempt is making at Athens, the present capital of the modern Greek empire, to organize a medical school, by several well educated and respectable Bavarian physicians and surgeons, who are attached to the court, and whom King Otho has induced to settle in his country. At the time of my visit, (April, 1838,) they had

from nine to twelve pupils, natives of the country, who were lectured to by the Germans in the modern Greek language; the professors, from a residence of several years in the country, being able to impart instruction to the pupils in their native tongue. Although it is the merest beginning of a medical school, it is nevertheless praiseworthy and honourable to its present founders, and may be the germ of an institution which shall move onward hand in hand with the regeneration of poor fallen Greece. It may be, that from this embryo of a medical school, in far distant time, the continent and islands may echo again with the fame of another Hippocrates, an Erasistratus, and a Heriophalus.

Athens possesses at this moment a most excellent military hospital, arranged upon the modern European plan, capable of containing very comfortably several hundred patients. Also a highly respectable and well arranged cabinet of Natural History.

Even in the mighty capital of the Ottoman empire, Constantinople, the light of medical science is beginning to dawn. A medical school is already commenced, under the sanction of the noble and enlightened Sultan Mahmoud. The teachers are all Europeans, mostly Italians, and they are giving instruction to from fifteen to twenty native pupils.—*American Journal of the Medical Sciences.*

## POISONING BY MUSHROOMS.

ON the 1st October, 1838, M. O. the father of a family, collected some mushrooms, which he said were of a good sort, in an orchard bordering on a sheet of water near his house. They were plucked, cut into bits, and steeped in water; they were then boiled in oil with sweet herbs, and made a large dish, which was served up at dinner at six o'clock.

M. O., the father, ate some before they came to table, and very plentifully at dinner.

M. O. the son, ate the greatest quantity next to his father.

Madame O., the mother of the family, of a weak constitution, and living very temperately, ate but few.

The grandson of M. O., aged six, ate a good many for his age.

Mademoiselle Julie, the niece of M. O. had but few, and Rose, the cook, tasted them while stewing.

The following were the symptoms experienced by each person:—

M. O., the father, passed the night well, and went out, feeling better than ever, at six in the morning, to walk in the park.

About eight he felt uncomfortable; anxiety and nausea came on, and then vomiting of mucous and greenish substances, with bits of undigested food; with copious half-liquid stools, containing fragments of a spongy appearance. The vomitings were succeeded by retchings, with general weakness, coldness of the extremities, paleness of the face, burning thirst, and dryness of the throat and mouth. During the night, cramps came on in the calves of the legs and soles of the feet; the face was contracted, the limbs cold and livid; the urine was suppressed; and the pulse vanishing. From time to time there were intervals of sinking, but without drowsiness or delirium, and the patient was perfectly himself.

On the 3d, the cramps and vomitings had ceased; the liquid stools continued, but were less frequent; there was less colic; no pain in the head, and but slight tendency to drowsiness. Towards the evening, during the night, and particularly on the morning of the 4th, the symptoms, which had seemed to diminish, became frightfully intense; the alvine evacuations, though less frequent, were tinged with deep black blood.

Towards 6 in the evening, the debility made rapid progress, yet the patient still preserved his recollection. In spite of the active employment of stimulants, he sank, after a death-struggle which lasted thirty or forty minutes. M. Pallois [who narrated the case], did not see him till the 2nd, after the vomiting and purging had probably carried every particle of food out of the alimentary tube.

M. O., the son, was attacked on the 2nd, at daybreak, with vomiting, and had copious stools with but little colic. Repose, and the use of soothing drinks, and emollient clysters, were prescribed. Under the influence of these remedies, the symptoms, which were at first attributed to mere indigestion, lost their severity; but for five days running, the patient experienced retchings, mucous stools of greenish and blood-stained tints, coldness in the limbs, tendency to swoon, and considerable thirst, with dryness of the mouth; the pulse was very weak, but regular; there was a notable diminution of the urine, and considerable agitation with slight delirium during the night. These symptoms gradually increased. On the 4th day a stool was passed, consisting of blood almost entirely pure; yet there was a remarkable mitigation of the other symptoms, with a little diaphoresis during the night.

It was not till the evening of the 6th of October that the patient could be considered as out of danger; but he was still very weak, and passed liquid stools, the

colour of which, however, sensibly improved. He was not convalescent till the 8th.

During the course of his disease the symptom which harassed him the most was a want of sleep, which was not relieved by the slight narcotics given him.

Madame O. passed the night following the poisoning without feeling any inconvenience, but was severely ill afterwards. However, she experienced a fortunate reaction; the vomitings and purgings having entirely ceased. On the fourth day she was attacked with feverishness; and on the 6th of October, a bleeding from the arm to four ounces cured a dull and wearying headache.

The child, for three days, was seized with vomiting when he drank, and had watery stools of a greyish colour, without much colic; he continued weak and pale, and began to take a little light food about the fifth day after the accident.

Mademoiselle Julie had only frequent liquid stools of a greyish colour and fetid odour, with colic, nausea, and total loss of appetite: she grew pale and thin.

Rose, the cook, had several liquid stools without any bad consequence. The remains which she threw away in the evening on washing the dishes having been eaten the following morning by a young hound, he died in ten or twelve days, with vomiting, agonising pain, and convulsions. A cat in the house had the same fate.

M. Pallois having gathered mushrooms in the same place as M. O., and being assured of their identity by persons who were present, soon saw that they were of the kind called *agaricus bulbosus* by Bulliard; *amanita viridis* by Persoon; and *agaricus phalloides* in Chevallier's Paris Flora.

Their popular names are *orange* and *petite ciguë blanche*, (small white hemlock), and their poisonous action is the more terrible, as it is not felt, according to Vaillant, till 12 or 15 hours after the mushrooms have been swallowed; an assertion which is completely verified by the preceding facts. — *Bulletin Méd. du Midi*.

## ON THE TREATMENT OF DISEASE BY COLD WATER,

IN THE FOREST OF THURINGIA.

THIS method was employed in England towards the end of the fifteenth century\* by Floyer. Long afterwards, in 1732, 38, and 43, it was imitated by Drs. Hahn, the

father and son. It is now eight or nine years ago, that a countryman named Vincenz Preisnitz, after having tried it upon animals, set up the first establishment of this kind at Gräfenberg in Austrian Silesia, with the permission of the government; he was not long without competitors, as there are now thirteen or fourteen of these establishments in Germany.

M. Sachs, who remained for some time at Elgersburg and Ilmenau, which are at the entrance of the forest of Thuringia, gives their topography, reckons up, pretty nearly, the number of bathers, describes the regimen which the patients are made to follow, and mentions some diseases which have been cured there.

The programme of the day is nearly the same in all these establishments. At four, or half past four in the morning, perspiration is begun to be produced, which is done by wrapping the patients, like babies in swaddling clothes, or like mummies, in large and thick blankets. Perspiration usually begins in an hour, and is kept up by making the patients drink several glasses of cold water every half hour. In many cases, when the perspiration is at its height, pieces of cloth dipped in cold water, and previously well wrung, are dexterously introduced under the blankets, and applied to the most diseased parts; these parts, as well as the cloths, grow hot, the perspiration soon begins afresh, and causes a sensation of burning in the part.

At the end of three hours the blankets and bed are soaked with perspiration; the patients are then conducted into a neighbouring room, or to another story, where they take their cold baths; and in doing this, they often pass through draughts of air without being inconvenienced. Before plunging into the cold bath, they wash their head and chest; and after staying in it two or three minutes, the patients take a few cups of milk with a little bread, and then walk out upon the mountains which border on the establishment, and drink cold water at the numerous springs which they meet upon their route. About nine or ten o'clock they take the douche, or else walk to the cascades which are in the forests or mountains, and expose themselves to the fall of the water that comes down from a height, and strikes the body with great force. Immediately after dressing, they again drink several glasses of water, and then walk in the open air.

It is natural that after such exercise the patients should sit down to table with a good appetite, and one easily sees that persons labouring under piles, or hypochondriacs, hysterical subjects, or overworked persons, must find in these establishments a cure which they would in

vain seek elsewhere. As to rheumatism, arthritis, cutaneous diseases, inveterate syphilis, &c., we will say with M. Hoffmann, *experientia præcedit, ratio sequitur*.—*Berlin Med. Centralzeitung*.

## STATISTICS OF TRACHEOTOMY.

Since the introduction of tracheotomy in croupal affections into France, there has, doubtless, been reason to deplore a great number of failures; it may be presumed, however, that one of the chief reasons of its insufficiency depends on the delay and the obstacles that are generally thrown in the way of its performance. The following are the results which the different most celebrated operators have by their own declarations, in a late discussion at the Royal Academy of Medicine in Paris, obtained.

## ON TORSION OF THE ARTERIES.

DR. REMAK recommends a modification of the operation of torsion of the arteries, which consists in seizing the vessel transversely with a pair of sharp wedge-shaped forceps, and then pressing forcibly, so as to divide the internal coat. The extremity of the artery is then seized with another pair of forceps, and twisted, while the torsion is prevented from extending up the artery by the first pair. The vessel is thus less injured than in the common proceeding, and the internal coat, which shrinks after being divided, offers an effectual barrier to the blood. The operation was tested experimentally upon a horse: the carotid was divided, and torsion performed as recommended above, was sufficient to restrain the hemorrhage, even when the horse was made to trot briskly.—*Medicinische Zeitung*, No. vi., and *British and Foreign Medical Review*.

## THE CROONIAN LECTURES

FOR 1839.

By JOHN CLENDINNING, A.M. & M.D.  
Of Oxford, &c.

As delivered at the Royal College of Physicians,  
May 15, 17, 22.

### ON THE DIAGNOSIS OF DISEASE OF THE HEART.

*Pulmonic complications.*—*Emphysema; Œdema.*  
—*Percussion should be studied first on the*  
*Dead.*—*Diagnostic value of Percussion.*—  
*Laennec too sanguine.*—*Hepatic compli-*  
*cation.*—*Jaundice.*—*Renal complication.*—  
*Encephalon.*

*Pulmonic complications.*—In the course of last year's observations I pointed out the great frequency of lung disease in chronic heart affections. I stated on that occasion, that in the great majority of my observations *post mortem*, omitting all reference to my much more numerous facts observed during life, I had found the anatomical conditions of chronic bronchitis, usually of both lungs and of every lobe, but often best marked in the lower lobes. I also stated that, in addition to the sub-inflammatory and hypertrophous condition of the bronchial lining membrane, I had, in a very large proportion of cases—a number considerably exceeding the half of the well-developed cases—met with those bronchial and vesicular morbid conditions described by Laennec as *emphysema* and *œdema pulmonum*. Further, I found that phthisis was associated with enlargement of the heart in a considerable proportion of cases, viz. in something like 12 or 14 per cent. of all the cases of cardiac hypertrophy ascertained *post mortem*; while some 10 per cent. had *pneumonia*, and something less *pleuritis*.

Now, with respect to the former, or bronchitis, including bronchial congestion with rhonchous breathing, whether with or without troublesome cough, according to my experience, it is quite a regular attendant upon, and may, in conjunction with others, be considered a very useful sign of, chronic disease of the heart. Traces of bronchitis are usually met with, according to my experience, in the hypertrophy of the heart from an early period. The tendency of the diseased heart to associate with itself a pulmonary catarrhal state is shewn in several ways:—

1. By their usual coincidence, as shewn by unequivocal symptoms, and morbid appearances in the class of confirmed cases. This has been already last year, and in the preceding pages, insisted on.

2. By the general liability amongst cardiacs, even in early stages, to cough, with the wheezing or otherwise noisy respiration of bronchitis over more or less of the chest, especially the central parts.

3. By the frequent coincidence of *morbus cordis* with the paroxysmal pulmonary congestion and neuralgic pectoral distress, with palpitations or other cardiac irregularities, that seem the principal immediate causes of the agonies of asthma.

The presence, then, of catarrhal symptoms, obvious or obscure, is a valuable rational sign of disease of the heart, subject, indeed, like all other functional lesions, to restrictions and exceptions in their application, but yet such as, in chronic pectoral disease, to strengthen very materially, or weaken, the probabilities of *morbus cordis*. In fact, I incline strongly to the opinion, that where phthisis or *pneumonia*, *pleuritis* or *bronchitis*, recently supervening on a previously sound subject of mature years, cannot be made out, the presence of a chronic pulmonary catarrh affords strong rational evidence, not to be overruled by any

thing less than satisfactory physical signs of a normal condition of the heart.

*Emphysema; (Edema).*—Not identical, but very closely connected with chronic bronchitis, are two morbid pulmonary conditions, which, like bronchitis, have been already adverted to under another head, but which it will be proper here again to notice shortly—namely, *emphysema* and *œdema pulmonum*. Of the frequency of coincidence of each of these morbid conditions with cardiac hypertrophy, enough has been already said to render it unnecessary here again to insist on it. Suffice it now to say, that few advanced cases of the disease have by me been found quite free from either complication. My object in alluding to them now is merely to point them out as auxiliary means in the detection of enlargement of the heart.

For this purpose a careful examination of the principal regions of the chest is always necessary. The parts most important to examine are—*for emphysema*, the apex and margins of the lower lobes; and for *œdema*, the more central parts of all the lobes. For the detection of either, both percussion and auscultation are equally recommended, so far as I know, by all recent writers on the diagnosis of pectoral diseases; but I imagine the apparent unanimity of authors on this subject is partly attributable to the involuntary practice of copying or borrowing of opinions, rather than to coincidence of results of independent observation; since I find it difficult to understand how several original observers should arrive, in an inquiry so surrounded with sources of fallacy, at conclusions so nearly identical. But, be that as it may, I can truly affirm, according to my observations, that for the detection, in persons not very corpulent, of either *emphysema* or *œdema pulmonum*, auscultation is of little use, except as an auxiliary of percussion. *Emphysema*, when fully developed, is detected almost at once, by the practised hand, by percussion alone; and in a considerable class of confirmed cardiac cases there is nearly equal facility in detecting *œdema*,—to those, at least, that have practised percussion, so as to familiarize themselves with the ordinary resonances of the different regions. The results of a few taps with the open hand, or on one or more fingers, as *pleximeters*, on the pectoral regions most liable to the morbid condition sought for, are, when taken in connexion with the history and rational signs, sufficient in such cases to determine, without auscultation, whether any extensive and important alteration of density be present in the lungs. But the familiar acquaintance with the normal resonances

just referred to is not easily acquired in the clinical ward.

*Percussion should be studied first on the dead.*—The best place for our first lessons in all those parts of the physical semeiology that do not, like the murmurs of the heart, involve vital actions that admit of no substitute or imitation, as necessary conditions of their development, is the dead-house; and the best subjects of observation are bodies of persons dead of known diseases. That this is correct will be obvious, when we consider what are the conditions of pectoral resonance—whether obscure and fleshy, or soft, loud, and hollow\*. The conditions are these; viz. an impulse from without is transmitted through a substance more or less porous and penetrated by gases; extremely porous, like *emphysematous lung*, or little porous, like *hepatized lung*, or moderately porous, like healthy lung; and with the reaction, or reflected impulse, a sound is sent back, and uttered at the surface struck upon; and the character of this sound is determined by the degree of porosity of the parts from whose reaction it emanates. Now this process, or genesis of sound, includes no vital act whatsoever on the part of the subject of observation. For any examination, therefore, of the condition of the pectoral viscera, that can be effected by percussion simply, the dead subject is obviously as suitable as the living, with these advantages, however, in favour of the dead—viz. that the pectoral porosity is uniform in the latter, as are likewise all the other physical conditions of resonance; whereas, in the living, the relative proportion of fixed and gaseous matter in the thorax is in a constant state of fluctuation, from maximum to minimum, and *vice versa*. And there is further in the dead subject this capital advantage for the uneducated ear, viz. that after full and leisurely examination of the chest, immediate application can be made, while every impression is yet recent, of the only test by which the accuracy of our inductions can be unequivocally ascertained, viz. inspection, manipulation, &c. of the organs whose density it is desired to test by percussion. And this line of observation is applicable to other parts of the pectoral diagnosis; for the like reasons might, *mutatis mutandis*, be urged in favour of the study *in mortuis* of the respiratory sounds, and of what is always of vast, and sometimes of paramount importance, viz. the degree of expansibility and permeability by air of the

\* See a paper, by the author, communicated to the LOND. MED. GAZ. for Jan. 7, 1837, "On Percussion, and the Causes and Conditions of Pectoral Resonance."

pulmonary lobules and substance in general; for the vital actions concerned in respiration may, to a great extent, be imitated as to their effect, by artificial inflation of the chest through the trachea, so as to produce all Laennec's rhonchi, and cause pulmonary penetration and expansion by air, perceptible to the ear, eye, and hand, and closely resembling the physiological actions. In the same way, *mutatis mutandis*, can the modifications of the voice be imitated with more or less ease and completeness. But to return from this digression.

*Diagnostic value of Percussion.*—For the detection of fully developed and extensive emphysema or œdema pulmonum, percussion is, therefore, for practical purposes, sufficient in persons of ordinary fleshiness, without auscultation or other aid than the history and present rational symptoms, such as cough, expectoration, occasional dyspœa, &c. But when, as frequently happens, owing to corpulence, &c. either of the diseases under consideration is suspected, and yet percussion is found not decisive of the question, auscultation may generally be advantageously employed as supplementary to, and in a great measure corrective of, other means. The object of the auscultator should be, the ascertaining the degree and extent of the permeability to air of the lung, by getting possession of which he is enabled to avoid important sources of fallacy, that in certain cases beset percussion employed alone as a test or physical sign of the density, whether normal or otherwise, of the lungs. For example, when percussion gives a hollow resonance, apparently but not certainly exceeding that of a healthy lung, the expansibility and diffusion of respiratory sounds in the part examined, as ascertained by the ear or ear-tube, shews whether the quantity of air that penetrates the lung is less than normal; and if less, we are entitled to conclude that emphysema exists. On the contrary, when the resonance is apparently less than normal, with rational signs indicating, though perhaps indistinctly, œdema pulmonum, the application of the ear or tube readily detects the respiratory sounds indicative of a penetration by air, such as would not occur in a consolidated lung; and under such circumstances we are warranted in inferring œdema.

*Laennec too sanguine.*—To an extent, such as just explained by examples, there can be no doubt of the value of auscultation in the investigation of the diseases under consideration; but any further advantage I have not been able to derive from the ear-tube in such cases. Several distinct modifications

of respiratory sound, that have been insisted on by Laennec, and on his authority, I imagine, for the most part, adopted by subsequent writers as diagnostic of emphysema and œdema respectively, appear to me of doubtful utility. Often and often have I heard that illustrious observer dilate on his rhonchuses and crepitations as the best of all signs, amongst other pectoral diseases, of those under present discussion. But whatever I may have thought in the Salle of La Charité formerly, as a student, I now, as a practitioner, think that it was a weakness on the part of that great pathologist not to be contented with making great discoveries, from a desire to excel also in small matters. It is to be regretted, I think, that after completing the discoveries of Avenbrugger, and adding others equally important, and much more various, curious, and interesting, of his own, he refused to rest, or to exercise his sagacity in pursuit of high objects in other unexplored quarters, leaving, as he well might be expected to do, the drudgery of details, and the pursuit (so to speak) of *deducibles*, to the host of satellite pathologists that followed in his train; but continued to labour to bring to minute perfection these precious inquiries, whose general success is his best monument. For though singularly gifted for observation, he has, among the hosts of individual phenomena passing under his notice, frequently fallen into errors, which, in numerous instances, even in his high and well-deserved authority, has not saved from detection and exposure; and has, I think I may say as a general remark, in his eager study of details, often lost sight of great and leading truths, discovered or best developed by himself. Of this observation we have exemplification in the exaggerated importance attached by him to certain modifications of the breathing sound, under the name of *rhonchi* or *râles*, and the comparative neglect shewn to the relative degrees of penetrability and expansibility in the different lobes and regions of the lungs, whether with or without unusual breathing sounds. Now the extent of diffusion of air in a lung in breathing, or the amount of its alternate expansion and collapse, are obviously direct measures of its normal or defective porosity and penetrability; whereas the character of the breathing sounds, or *râles*, can, at best, only indirectly elucidate the lungs' physical condition, and may, with a few exceptions, be presumed to be, as I have myself found them, fugacious, variable, and subject to so many sources of fallacy, that they may be said, in most cases,

to suggest the possibility, rather than announce the existence, of the organic conditions they have been held to indicate.

And if these critical remarks on the doctrines of the illustrious Laennec have any just application at all, they are to none more applicable, perhaps, than to his account of the signs of emphysema and œdema, detected by the ear-tube. The characters and mode of observation of those signs I studied for some time under the professor himself, and since then have had ample opportunities of further observation, and the conclusion I have come to is, that the auscultatory signs of Laennec are of little substantive value in the diagnosis of those pulmonary diseases that involve diminution of density, as emphysema; or increase of density, without carnification, as œdema; that in some such cases they will be found useful auxiliaries of percussion and other signs; but that in no case (except *incipient pneumonia* or *bronchitis*) can they be considered as principals, or otherwise rendered available than as subsidiaries to the use of the pleximeter, &c.

*Hepatic complication.*—*Hepatic enlargement* is another feature of cases of *morbus cordis* much insisted on last year. The occurrence of this complication I was able to shew, by a large induction of my own, confirmed by reference to several authors of weight and authority. In fact, it is rarely absent in decided enlargement of the heart. The position of the liver with respect to the lower margin of the ribs, is, I think, the usual test by which the development of the liver, whether morbid or otherwise, is judged of. It is commonly held that if the organ project far towards the umbilical region, from under the ribs, it must be abnormally large, and this even, I think, in the absence of any well-marked inflammatory tenderness in the hepatic region. Of the upper boundary, however, of the organ's place, no account is usually taken. Thus it is plain a large liver well sustained superiorly, or strongly pressed upwards by tympanitis or ascites, might pass for small or normal, and a small liver pushed down by pleuritis or emphysema above, or by stays outside and around, might pass for abnormally large; and the fallacies arising out of this variability in the liver's situation can only be avoided in doubtful cases, by careful measurement by percussion, of the extent of the hepatic region actually occupied by the liver. By such means we can usually with ease satisfy ourselves of the hepatic developments, and can, in suspicious and doubtful cases of chronic pectoral disease, very often obtain valuable presumptive evidence.

From the researches so often alluded to, it appeared that hepatic enlargement was a common complication of phthisis, though to a less extent than in *morbus cordis*. The presence, therefore, of excessive hepatic developments will not, if phthisis be not excluded, contribute much as a rational sign towards cardiac diagnosis. It is true that phthisis and *morbus cordis* are pretty often combined, and the combination is often extremely embarrassing, owing to the number of points both as to physical and rational signs that are common to both diseases. But the distinctive characters, even though in combination, are not often difficult to trace; for there has been hæmoptysis, perhaps, and the breathing and perhaps the voice, may denote a cavity; or there is a circumscribed dulness of resonance and inspiration, at each or either apex, especially in the subclavian or axillary or supra-spinous regions, or in all three; while the lower lobes afford more nearly normal resonance and murmur than the upper. Then as to *morbus cordis*, there is perhaps an abnormally extended ventricular impulse, or an abnormal excess or defect of valvular sound; and at all events, there is, if heart disease be present, an unusual extent of dulness in the cardiac region; or other sign or signs, rational or physical, of *morbus cordis*. So that any hepatic enlargement occurring in a suspected disease of the heart complicated with phthisis, would be more or less available as a rational sign of the former, notwithstanding such complications.

*Jaundice.*—Of the hepatic disease under consideration, when doubted of, owing to want of practice on the part of the observer in the mechanical method of diagnosis, or to other causes, the occurrence of Icterus affords not unfrequently useful confirmatory though indirect evidence. Doubtless a transitory retention or re-absorption of bile may happen with a normal hepatic development; but in organs of low vital power, and sluggish sensibility and circulation like the liver, well-marked and important functional lesion rarely arises from slight causes, and is rarely unconnected with morbid visceral conditions, involving excessive, if not otherwise vitiated nutrition. And in accordance with this view, I think it will be found, that the occurrence of jaundice in the course of chronic pectoral disease of an asthenic character is a rational sign of an hepatic enlargement, dependent on and indicative of cardiac disease, of not less value than many sympathetic functional lesions handed down from antiquity as pathognomonic, and still had in good repute.

*Renal complication.*—Not only are the heart and liver enlarged in morbus cordis, but my observations shew that the kidneys also become abnormally developed. Of this likewise I produced last year some confirmatory evidence from authors of authority; and to these already named and referred to, I might add the distinguished name of Dr. Christison, who from his recent work on the Kidneys, seems to have often seen, if I rightly recollect, the renal enlargement under observation. But though the connection between morbus cordis and renal disease is pretty well established, still the situation of the kidney, deep-seated and inaccessible as it is, would too frequently put it out of our power to make any use of the renal complication as a sign, were it not that the secretions of the kidneys are apt to suffer change while the kidney is being over nourished, and that Albuminuria is a very common attendant on cardiac disease. On one occasion I examined on the same day the urine of several persons who had cardiac dropsy, amounting to some half dozen or eight persons, and with one exception only found the urine albuminous in every instance. The exceptional case it is right to state was a well marked case of heart-disease. The frequency of coincidence, then, of albuminuria with disease of the heart, is sufficient to constitute it one of the signs of that disease. This position has already been virtually laid down by Dr. Christison, who has observed very generally that the renal disease called "Bright's Kidney," involves or implies disease of the heart. Professor Christison indeed is so strongly impressed with the closeness of the relationship between those diseases, as to have conceived like myself that one is the cause of the other. To the question, however, which is effect, and which cause, he has, I regret to perceive, given an answer nearly or exactly the reverse of what I should have given. Dr. Christison's opinion seems to be that the cardiac enlargement is an effect of the renal disease. What the grounds of that opinion are, he has not, I think, distinctly stated. But whatever they may prove to be when published and open to remark, I am prepared to avow before hand, my conviction, that like every thing that I have yet seen from the same pen they will be found to deserve an attentive and respectful consideration.

*Encephalon.*—The next important complication commonly met with in cases of old heart disease is hypertrophy of the brain. Of this coincidence of cerebral and cardiac disease I adduced last year experimental evidence, both from the ob-

servations of my late lamented colleague, Dr. Sims, and from my own, which, in the absence of any countervailing facts, may be held to be provisionally decisive of the question. For the present I shall assume the connection as proved, and proceed to make a few observations upon it as a rational sign of heart disease. Before doing so, however, I may be allowed to observe, that I have as yet been unable to satisfy myself as to the mode in which the adventitious cerebral matter is most generally distributed; whether the brain so hypertrophied is enlarged in volume or increased in density. The results of thirty or forty observations were communicated to the College last year, but it was at the same time stated, that I was by no means satisfied of the trust-worthiness of those results as correct averages, or even very close approximations to correct averages. Since that time circumstances already distantly alluded to have interrupted my researches during considerable periods, and I have been as yet unable to repeat my experiments relative to specific weight sufficiently to obtain the additional data required. The problem, however, is one of some importance, and I shall persevere in searching for facts, until I shall feel myself in a situation to solve it.

But to revert to the subject of cerebral hypertrophy as a source of functional lesions indicative of cardiac disease, the following may, I think, on that point, with much confidence be stated, viz. that the frequent occurrence, in the course of pectoral diseases, not clearly wholly phtisical, of head symptoms indicating encephalic plethora, whether arterial or venous; for example, such as headache, vertigo, tinnitus aurium, ocular spectra, vague sensations about the head of rushing, heat, noise, &c., or of the graver symptoms of convulsion, coma, &c., implies, in the great majority of instances, increase of weight and volume in the heart; also, that the proportion of ascertained heart cases in which symptoms the same, or of the same meaning with those just mentioned, have not appeared, is so small, comparatively speaking, that there need in my judgment be no hesitation about adding such cerebral functional lesions to the number of the rational signs of morbus cordis. And the weight of such probable evidence of heart disease is the same, I conceive, whether the vital condition of the heart be sthenic or the reverse. For except in intensity and urgency, there does not appear to be any important difference between the cerebral effects of venous and arterial plethora. Either may lead to inflammation or hæmorrhage, and

either may, of course, be a cause of any of the cerebral functional lesions above named.

With respect to the influence that might be supposed to attach to one side or one ventricle of the heart, more than to the other, I am not aware that any such difference of influence is of much importance. An important morbid change in either ventricle is, sooner or later, sure to derange more or less the cardiac action in every part, and through their centres, the ventricles, to spread disorder over both lesser and greater circulations; so that though disease commence on the right, the morbid action will soon extend itself to the left also; and if it begin, as it commonly does, on the left side, the right cannot be expected long to continue exempt. And thus, whatever may be the starting point, the cerebral circulation at first, and ultimately the cerebral nutrition, appears to become affected.

In this respect the brain seems to stand in the same relation to the diseased heart as other viscera, of all of which it may, and so far as I can see without important exception, be observed, that their increased development occurs nearly equally, whether the right or left side appear to be principally diseased.

Three or four other topics remain still to be observed upon, viz., the pulse, sex, age, and dropsical complications.

### SEQUELE AND COMPLICATIONS OF KERATITIS.

*Acute iritis.—Symptoms.—The various forms of iritis.—Causes of acute iritis.—Termination of iritis.—Prognosis.—Treatment of acute iritis.—General treatment.*

#### *Acute Iritis.*

ACUTE inflammation of the iris may commence either by the anterior or serous, or by the posterior or uveal surface of the organ, or by its parenchyma. I shall, however, lay but little stress on the symptoms which distinguish these shades of inflammation, as in the present state of science the distinction can be but of very

slight importance in a practical point of view. Indeed, in a membrane so thin as the iris, inflammation cannot long remain confined to one region; it must at an early period invade the entire membrane.

Acute iritis may be considered to present three stages. Were there but few symptoms present, such a division would be useless; but as the symptoms are on the contrary extremely numerous, it will prove an useful adjunct to the memory.

*Symptoms.*—The symptoms of iritis are generally divided into two classes—the anatomical and the physiological. The anatomical symptoms are those that can be appreciated by the eye of the surgeon; the physiological symptoms are those that depend on functional disorder of the organ, most of which can only be appreciated by the patient himself.

The anatomical or objective symptoms are numerous, and may also be divided into two classes; those which are to be referred to the inflamed organ, and those which are furnished by the adjoining tissues; such as the sclerotics, the cornea, the conjunctiva, the anterior chamber, &c. The symptoms which are given by the iris itself are more difficult to appreciate than those which we observe in keratitis; they are, indeed, in many instances, so fugacious, that until you have often seen the disease you will find it difficult to recognise their presence. They depend on the diameter of the pupil, on its form, its mobility, its colour, its thickness, and on the appearance which its surface presents. In the first stage of the disease, which may be said to extend over the two or three first days, the pupil contracts slightly, and loses in some measure its mobility, without, however, there being any visible alteration in its form. When the inflammation occupies one eye only, you will at once perceive the change that has taken place by comparing it with the other; but when both are affected it becomes extremely difficult to discover whether the pupil is or is not contracted; and were there no other symptom, the diagnosis would be very uncertain. As, however, the mobility of the pupil is always impaired when the iris is inflamed, it is possible to ascertain the real state of that organ by exposing rapidly to the light the eye, previously obscured for a few seconds. If the iris is healthy it immediately contracts; if, on the contrary, it is the seat of inflammation, contraction does not take place, or is very imperfect. As the inflammation increases, the contraction of the pupil appears more decided; it becomes at the same time perfectly immoveable, and the various preparations of belladonna lose nearly entirely the influence they exercise over its motion

in the healthy state. The colour of the iris also undergoes modifications which ought to be attentively studied, although they are not of the extreme importance which they are supposed to be by the German ophthalmologists. The iris presents three zones or rings, one of which is situated near the pupillary or inner circumference of the organ, another near the ciliary or outer circumference, and the third is intermediate. The colour of the pupillary zone becomes modified before that of the external and intermediate zones, the nature of the change which takes place varying with the natural colour of the iris. Thus, it assumes a greenish tint when the iris is naturally blue; becomes, on the contrary, brown when the iris is grey, and brick-red when the iris is brown. These various hues also soon become visible on the ciliary zone. Between the two may be seen a network formed by numerous small vessels, which converge as they pass from the outer to the inner zone, and are crossed transversely by other vascular filaments. When the inflammation is acute these vessels become more and more injected, and form a red zone between the two, which I have just described.

The texture of the iris is also modified, that organ becoming turgid, and thicker than in the natural state. Its anterior surface, which when healthy is smooth and polished, seems as if it had been macerating in some fluid, the small furrows which it presents disappearing, or otherwise it assumes a velvety appearance, and presents numerous specks of different colours.

The iris itself is not the only organ that is modified when it is the seat of inflammation; the adjoining tissues always undergo more or less alteration. The transparency of the cornea is slightly impaired. The scleroticæ presents the vascular radiated zone which I have already described as a symptom of keratitis; but it is much less manifest than in that affection, unless, however, the iritis be accompanied by inflammation of the cornea. This radiated zone does not advance on the scleroticæ as far as the cornea, from which it is separated by the arthritic circle. The conjunctiva is in general but very slightly injected.

The physiological or subjective symptoms are also of great importance in forming our diagnosis of the disease. From the first the patient feels pain, more or less severe, in the orbit, as also in the forehead and temples. If the inflammation becomes intense, he often complains of throbbing in the eye, and of an extremely painful sensation of distension of that or-

gan. Fear of light, and shedding of tears, are also observed at an early period of the disease, but these symptoms are seldom as intense as in some other inflammatory affections of the eye, as, for instance, in ulcerated keratitis. M. Sichel does not allow that photophobia and epiphora are symptomatic of iritis, and says that when they are present it is because the iritis is accompanied by retinitis. But his views on this subject are certainly erroneous; it is extremely rare to meet with a case of iritis that does not present photophobia and epiphora to a certain extent: as might be anticipated, from the anatomical symptoms of the malady, vision is always more or less disordered.

The general symptoms in iritis are very variable: sometimes there is no reaction whatever; sometimes, on the contrary, there is fever, thirst, loss of appetite, &c.

The second stage of the disease is characterised by the exacerbation of all the symptoms which I have enumerated; the diagnosis, therefore, becomes much easier. The contraction of the pupil gradually increases; and, losing its circular form, it assumes an angular shape. This change in the form of the iris constitutes one of the surest and most convincing proofs of the existence of iritis, and when it is observed it is next to impossible not to recognize the nature of the disease. We cannot, therefore, be surprised that German ophthalmologists should have made it one of the principal characters by which the various specific forms of iritis which they describe may be distinguished from one another. When the form of the pupil is thus altered, it may represent a lozenge, an oval, an ellipsis; indeed, it may assume nearly every possible variety of shape, the modifications which it thus undergoes depending, according to their ideas, on the cause which has produced the iritis. Were this opinion correct, we should be able, by the examination of the eye alone, to say that the iritis has been produced by such or such a cause, and that it belongs to such or such a form of inflammation. But this is not in reality the case; the changes which occur in the form of the iris have no connection whatever with the cause that has given rise to the iritis; they are merely to be attributed to the tumefaction of one region of the iris being greater than that of another region, or to adhesions having been formed, which impede its movements. We have now in our wards four or five patients labouring under iritis who present this symptom, yet you will not find one out of the five with whom the iritis can be possibly ascribed to the cause which ought to have produced it, were the views of the German school on

this subject correct. Indeed, the pupil of one of them has presented successively, in the course of a few days, all the principal modifications of shape which characterize the four chief forms of specific iritis—that is, the syphilitic, the serofulous, the rheumatic, and the arthritic forms of that disease; and as we have continually facts of this kind under our eyes, it is really impossible to admit that the form which the pupil assumes, when inflamed, depends on a specific cause.

The humours of the eye losing their transparency, the colour of the pupil changes. Flakes or filaments of coagulable lymph often make their appearance, extending from one part of the pupillary circumference of the iris to another, and interlacing, so as to form all kinds of figures. Sometimes these flakes are only partly attached to the inner margin of the iris, or even float quite free in the pupil. It is nearly always very difficult to bring about the absorption of the lymph which has thus been effused, and as by its presence in the pupil it intercepts the entrance of light into the eye, the functions of vision are materially impaired. There can, in my opinion, be no doubt that these changes in the transparency of the pupil are due to the effusion of plastic lymph, which takes place as a consequence of the inflammation of the iris. This membrane, situated as it is in the centre of the anterior chamber, may be compared to a fire placed in the middle of a room, the caloric emanating from which must necessarily modify the bodies that surround it.

In some instances, the naturally smooth surface of the iris presents numerous folds or furrows, as also well-defined specks and patches, which are to be attributed to ecchymosis, or to the effusion of purulent matter into the tissue of the organ. The patches are slightly raised above the level of the surrounding parts of the iris, and are encircled by a yellow areola. The specks are either of a brown or of a yellow colour, and protrude more or less into the anterior or the posterior chamber. When these symptoms are observed the iris seldom retains its usual situation; it is generally pushed either forwards towards the cornea, or backwards towards the crystalline lens. This phenomenon has been described under the name of *synechia*, anterior and posterior, and is caused by an increased secretion of the humors of the eye. Thus, when the vveal surface of the iris is first inflamed, the aqueous humor in the posterior chamber is increased, and the iris being pushed forwards, anterior synechia is produced; this also occurs when the volume of the vitreous humor is augmented. When it is the anterior surface

of the iris that is first inflamed, the aqueous humor in the interior chamber is increased, and the iris being pushed backwards, it is posterior synechia that is produced. Synechia may also be caused by the adhesions which the iris contracts with other parts of the eye. It will be anterior when it adheres to the cornea, posterior when it adheres to the crystalline lens.

When the iritis is intense, in this stage of the disease the inflammation often extends to the conjunctiva. The transparency of the cornea becomes more and more impaired, and the radiated sclerotic zone appears wider and of a deeper red. In some instances this zone advances as far as the cornea, the vessels by which it is formed losing themselves in the superficial lamellæ of that organ; in others, it stops at the union of the cornea with the sclerotic, and in others again it remains separated from the cornea by a grey or blue ring, as in the first stage.

At this period the pain felt in and about the eye may become very severe. It appears to extend more especially in the direction of the branches of the facial nerve, and of the fifth pair. The photophobia and the epiphora generally increase; sometimes, on the contrary, they become less intense. The exacerbation of the latter symptoms is occasionally accompanied by fever, nausea, and even delirium, but this is not often the case. It is worthy of remark, that there is seldom much general reaction in iritis, even when the inflammation is violent. Iritis differs in this respect from conjunctivitis and keratitis.

In the third stage of the malady we meet with all the symptoms that I have already described, but they are even still more evident than in the second stage. The contraction of the iris is sometimes carried so far as entirely to close the pupil, and the irregularity of its contour becomes more and more manifest. Attached to the pupillary circumference are numerous filaments or fringes, which also greatly tend to modify its form, and the flakes of coagulable lymph contained in the pupil are in some instances so numerous as entirely to conceal it. When this is the case, they may present all the characters of false membranes, and give rise to false cataract. The colour of the pupillary zone undergoes considerable modification, the iris assuming in this region a greyish or yellowish tint. During the inflammatory period of the malady the congested state of the vessels renders the iris darker than usual, but these vessels becoming to a certain extent obliterated, the paler fluids alone remain. The change which takes place in the colour of the iris is not, therefore, to be attributed to the decomposition of the

blood, but to the solidification of the lymph which has been effused.

It is more especially in this period of the disease that we meet with specks, ecchymosis, abscesses, purulent or sanguineous collections. Effusion of blood may take place in the tissue of the iris to such an extent as to reach from the larger or outer circumference of that organ to the pupillary margin. The iris is also often the seat of small abscesses, which may be easily recognised, especially when situated at the free edge of the pupil. They are often very numerous; indeed, I have seen as many as twenty-eight in the same eye. The synechia is more decided than in the second stage; and when the disease has arrived thus far, it has generally been long accompanied by inflammation of the cornea and conjunctiva. The symptoms which indicate that these affections have existed for a considerable length of time are, therefore, often observed. The alterations which occur in the aqueous humour might possibly lead a person unacquainted with the nature of the disease to believe in the existence of hypopion. Such an error, however, will never be committed by those who have practically studied the symptoms of iritis.

*The various forms of iritis.*—Iritis may, as I told you in a former lecture, occupy the anterior or posterior surface, or the parenchyma of the iris; but the distinction between these forms of inflammation can only be made at the commencement of the disease, the extreme tenuity of the membrane not allowing inflammation to exist long in one region without extending to the remainder of the organ.

*Serous iritis*, in which the anterior or serous surface is the seat of inflammation, may be easily distinguished from uveal iritis. The surface of the cornea is bathed with fluid, and assumes a peculiar shining appearance which it does not present when the eye is in a healthy state. This peculiar appearance of the eye must not, however, be confounded with the epiphora or effusion of tears, which is met with in ulcerated keratitis. On raising the eyelids, which may be done without any difficulty, we merely find the eye presenting a moist, watery aspect. In ulcerated keratitis, on the contrary, the contraction of the eyelids is so great as often to render it nearly impossible to open the eyes, and as soon as the cornea feels the contact of the air, the tears flow in abundance. In serous iritis the cornea also presents the greenish tint, but as the other symptoms of keratitis are absent, the nature of the disease can scarcely be mistaken. The surface of the inflamed membrane no longer appears smooth, as

in the healthy state, and the transparency of the aqueous humour is modified. If you then examine the eye attentively, you will frequently perceive small specks or dots apparently situated on the internal surface of the cornea—a proof that the posterior lamella of that membrane is inflamed. This extension of the inflammation from the iris to the cornea is the necessary consequence of the anatomical disposition of the parts. The anterior chamber being lined by a serous membrane which exists both on the anterior surface of the iris and on the posterior surface of the cornea, it evidently follows that when one region of the membrane is inflamed, the inflammation must soon be propagated to the rest of the organ, as is nearly always the case with serous membranes. In pleurisy, for instance, if the inflammation begins by the costal pleura, it soon extends to the pulmonary pleura, and in peritonitis, if it begins by the parietal peritoneum, it soon extends to the visceral layer of that membrane. In this form of iritis the pain is but slight. If the inflammation persists, the aqueous humour contained in the anterior chamber increases, and the iris being pushed backwards, posterior synechia is produced. The anterior chamber then appears larger than usual,

In *uveal iritis*, the shining, watery appearance of the cornea is not so well marked as in the preceding form of inflammation. The pain is more severe, of an inflammatory nature, and radiates to the different parts of the head and face. The greater violence of the pain may be easily accounted for when we consider that the uvea is prolonged on the retina, and is in immediate communication with the nervous system of the head. The pupil becomes troubled sooner in serous iritis; indeed, this form of inflammation is nearly always accompanied by more or less effusion of lymph in the pupil.

I shall not attempt to assign peculiar symptoms to *parenchymatous iritis*. It is extremely difficult, if not impossible, to separate it from the other two forms of inflammation. We may admit isolated inflammation of the surfaces of the iris, for we know that mucous or serous surfaces may be inflamed without the subjacent tissues participating in the inflammation, but in a membrane of such extreme tenuity as the one in question, it is scarcely possible for the parenchyma alone to be affected.

Did I not intend very shortly to treat at length the subject of specific ophthalmia, it would now be time to examine the various forms of inflammation which are described under the head of scrofulous, rheumatic, arthritic, and syphilitic sore

iritis. Suffice it for the present to say that syphilitic iritis is, in my opinion, the only specific form of the disease which can be said to exist, and that all the other inflammatory affections which have been recognized by ophthalmologists ought to be erased from our nosological categories, as they only exist in the imagination of those who have described them. I shall, however, defer, for the present, the examination of the characters which warrant our recognizing syphilitic iritis, merely observing that, although I admit the existence of this specific form of inflammation, I by no means recognize as symptoms of such an affection those characters which are generally considered to indicate its presence.

*Causes of acute iritis.*—The anatomical nature of the iris is such as alone satisfactorily to account for its being so frequently the seat of inflammation: indeed, it is probable that it would be much oftener inflamed than it actually is, were it not guaranteed, by the position it occupies, from numerous causes of inflammation to which the superficial tunics of the eye are exposed. The internal causes of iritis are not well known. Great influence has been ascribed to sudden change from heat to cold—to meteorological phenomena—in fine, to all those agents which are supposed to act injuriously on the economy. But these are general causes of disease, and not more likely to produce iritis than any other malady. We continually see persons pass from a warm country to a cold one, from a warm to a cold room, without being on that account attacked by iritis; but of ten persons who expose themselves to cold when in a state of perspiration, some will be attacked by one disease, and some by another; one, for instance, by rheumatism, another by pneumonia, another by iritis; whilst some will suffer no injury whatever. The appearance of one disease sooner than another, when we are exposed to the agency of these general causes, seems to depend on individual predisposition, the nature of which we are not able to determine.

With the local causes of iritis we are much better acquainted. In operating for cataract by couching, the iris is often wounded, and iritis produced. This is also frequently the case when extraction is resorted to after the operation for artificial pupil, and in contused or punctured wound of the eye. Some surgeons consider the iris to be endowed with extreme sensibility, and are alarmed at the very idea of touching it in the operations which are practised on the eye. Thus Beclard says that couching scarcely ever succeeds when the iris is touched with the needle, the

mere contact giving rise to acute inflammation; and that were it possible to perform the operation without touching the iris, it would nearly always succeed. But when we operate for cataract by extraction, the crystalline lens, in passing through the wound of the cornea, must necessarily drag or tear the iris; and yet it is not so much iritis that is feared as the inflammation of the cornea which ensues, and the opacities by which that inflammation may terminate. Nor is the operation as unsuccessful as we should be inclined to consider, were we to adopt these opinions. Some practitioners say that they succeed in half or in three-fourths of the cases in which they operate. The efficacy of the method of operating which they adopt, may have been exaggerated, it is true; as is nearly always the case when an exclusive opinion is professed: we are, nevertheless, authorized to conclude, from these statements, that what has been said of the exquisite sensibility of the iris cannot be perfectly correct. I have myself very frequently seen the iris cut or torn without its being consecutively inflamed. When, therefore, the iris becomes inflamed after local injury, the inflammation cannot be considered to depend entirely on the lesion it has received.

*Terminations of iritis.*—Iritis may terminate in several ways: by resolution; by the formation of false membranes, or adhesion of the iris to the surrounding tissues; by transformation into some other disease; or by suppuration.

Resolution is the most frequent and at the same time the most desirable termination of iritis. When it takes place the inflammatory symptoms gradually become less acute. The redness of the conjunctiva, as also that of the radiated sclerotic zone, diminishes, and at last entirely disappears. The iris appears less tumefied, and again assumes the smooth appearance which it presents in the healthy state. The external and internal zones return in a great measure to their natural colour, the pupil recovers its mobility and its regularity of form, and the cornea, as also the aqueous humour, again becomes transparent. The clarification of the aqueous humour is, indeed, one of the first symptoms which announce the resolution of the inflammation, and when it takes place we are justified in making a favourable prognosis. The false membranes, the flakes of coagulable lymph, are gradually absorbed, and the collections of blood or lymph which occur in the tissue of the iris itself, and of which I have already spoken, become flattened, circumscribed, and are finally resolved.

The resolution is not, however, always

as complete after acute inflammation of the iris, as I now describe it to be. The abscesses may leave indelible marks, the coagulable lymph which is effused in the pupil may not be wholly absorbed, and the iris may not entirely recover its mobility. Indeed, when adhesions have been formed, the resolution is seldom perfect.

There are two forms of adhesion of the iris. Adhesion may exist between the iris and the adjoining tissues, thus giving rise to the synechia of pathologists, or it may exist between the fibres of the iris itself. The iris is formed by a great number of circular and radiated fibres, which are supposed by some physiologists to be muscular, but in my opinion their views are erroneous. Whatever may be their nature, these fibres, which act separately and are naturally very moveable, may become united with one another in such a manner as to lose partly or even entirely their usual mobility. I cannot give you a better idea of the nature of the union that takes place than by comparing it to that which would occur between the fingers of the hand, were they kept in close approximation when violently inflamed. You may not all feel inclined to recognize the existence of this species of adhesion, but on consideration you will find that it is only by allowing that adhesion does take place between the fibres of the iris, that we can satisfactorily explain the coarctations of the pupil, coarctations which we often observe even when the iris has contracted no adhesion whatever with the adjoining tissues. We have at the present time in our male wards a case which will illustrate this form of adhesion, the coarctation of the pupil being carried to a great extent, without there being any apparent connexion between the iris and the organs placed posteriorly. The patient, a man of about fifty years of age, was affected with acute iritis of the left eye, several years ago, and the pupil was so contracted when he entered the hospital, this day fortnight, that it would scarcely have admitted the head of a large pin. Under the influence of belladonna, the pupil has become slightly enlarged, and has assumed a triangular form, something similar to an ace of clubs. The other eye is at the present time the seat of chronic inflammation, and it is for the affection of this eye that he entered the hospital. The pupil is irregular, and presents a margin prominent in some parts, slightly depressed in others. Those portions of the pupil which are depressed seem as if they were drawn back by something, whilst those which are prominent are apparently quite free. This case alone will enable you to form a very correct idea

of the various modifications which adhesion of the iris may present.

The adhesion which takes place between the iris and the adjoining tissues also offers two forms, which I have already briefly described to you under the names of anterior and posterior synechia. In anterior synechia the iris may adhere to the cornea either by its entire papillary circumference, or by a few points only. This kind of adhesion is rare, and when it exists the size of the anterior chamber appears much diminished. Posterior synechia is much more frequently met with, nor can we be surprised that this should be the case, when we consider that the distance which separates the iris from the crystalline lens is extremely slight. When the iris is inflamed it becomes tumefied, and the aqueous humour in the anterior chamber at the same time increasing, it is pushed backwards towards the lens. If the inflammation does not subside effusion of lymph takes place, as we have already seen; the aqueous humour becomes troubled, and small filaments soon form, which, attaching themselves to the posterior surface of the iris and to the anterior surface of the crystalline lens, constitute a connexion between the two organs. This form of adhesion may be easily recognized by rapidly raising the eyelid, previously closed for a few seconds, and then examining the eye. The pupil dilates when the eyelid is closed, but unequally, so as to assume every possible variety of shape. In some instances the adhesion takes place in another manner; the pupillary margin is connected with the crystalline lens by small filaments like hairs, a quarter of a line or half a line in length, which, tying it down as it were, occasion small triangular depressions wherever they exist. In all the forms of adhesion which I have described the functions of vision are more or less impaired.

Sometimes, when the iris has partly recovered its mobility, we see at the bottom of the pupil, near its circumference, a radiated ring. This ring is of a blackish colour, and may be compared to the sclerotic zone, of which I have so often spoken. When it is present the sight is always more or less disordered. Its existence is a proof that the inflammation has occupied the parenchyma of the iris, that pigmentum has been secreted in great abundance, and that the pupil, having rested on the anterior surface of the crystalline lens, has left this trace of its passage. Great attention has been paid to this phenomenon by German pathologists, who, to explain it, have invented a black radiated cataract. Indeed, the discussion on this subject has been rather warm, some asserting that the

zone was formed by vessels, others that it was formed by pigmentum. The black radiated ring in question may be easily produced in the dead subject by depressing the cornea—a fact which shows at once that the explanation I have given you is the true one.

After acute inflammation of the iris the resolution is sometimes so imperfect as to allow the formation of false cataract or of opaque membranes, which may constitute a complete obstacle to vision. I have often seen the malady thus terminate.

Iritis may disappear under the influence of the inflammation of the eye. Thus I have several times seen it give way when the cornea or the conjunctiva have become seriously affected.

Sometimes iritis terminates by suppuration, a circumstance much to be dreaded, from the disastrous consequences by which it is followed, with regard to the functions of the organ. When the iritis is extremely intense the whole interior of the eye may be attacked by phlegmonous or purulent inflammation; this general inflammation of the eye is called *ophthalmitis* by modern authors.

*Prognosis.*—From the description I have given of iritis, it is evidently a serious disease, not as regards the life of the patient, which is seldom in danger, but as regards the functions of the affected organ, which are often impaired even when the disease is cured. When, however, the treatment is begun sufficiently early, iritis frequently gives way, especially if there is no previous opacity of the cornea, and if the inflammation has not been cured by local injury.

#### *Treatment of Acute Iritis.*

Before we enter at length into the examination of the various remedial agents which are directed against iritis, I must remind you that a distinction should be made between primitive and secondary iritis; that is, between the inflammatory affection which commences by the iris, and that which is merely a consequence of the inflammation of some other organ. This distinction is important, as secondary iritis will often disappear when the affection by which it is caused has given way, and is often much less difficult to cure than primitive iritis. Local remedies also sometimes prove successful in secondary iritis, whereas they have little or no influence over the primitive form of inflammation.

The remedies which have been employed in the treatment of iritis are quite as numerous as those which have been used against keratitis, nearly every possible plan of treatment, both general and local, having been alternately tried, extolled,

and rejected. I have myself tried most of the remedial agents which have been directed against iritis at various epochs, and will now lay before you the result of my experience. In doing so, I shall follow the same plan as when treating of keratitis; that is, I shall first speak of the general, and then of the local treatment of the disease. As I have said nothing hitherto of the pretended specific forms of iritis, I shall not now allude to the treatment which they may require.

*General treatment.*—General remedies, as might be expected, from the situation of the iris, occupy the first place in the treatment of iritis. They may be divided into three classes—evacuants, alteratives, and resolatives.

At the head of the first class may be placed *blood-letting*, both general and local. Blood-letting is certainly the most powerful agent that can be directed against the disease, and, at the same time, the one the utility of which is the most universally recognized. But, although practitioners are unanimous in acknowledging the efficacy of the remedy, they are far from agreeing as to the manner in which it should be employed. Some prefer general, some local bleeding; some bleed copiously at several days interval, others bleed less freely, but repeat the operation oftener; whilst others, again, extol the plan of bleeding *coup sur coup*. Before we examine the comparative efficacy of these various methods, I must remind you that general bleeding may sometimes be contra-indicated by the individual state of the patient. Thus, it cannot be resorted to, or at least carried to any great extent, with patients of a lymphatic or serofulous habit of body, with those whose constitution has been weakened or deteriorated by disease, or by any other cause, or with those who appear to be in a state of anemia. When these contra-indications do not exist, general bleeding may be resorted to without fear. I do not, however, in any case, approve of the abstraction of a very large quantity of blood at the commencement of the disease, a plan recommended by some surgeons. Thus, Saunders advises the patient to be bled as soon as possible to the extent of two, three, and even four pounds. Such a mode of treatment is scarcely ever adopted in France. The loss of so large a quantity of blood may sometimes be useful, it is true, but it is, generally speaking, attended with very serious disadvantage. The patient is very frequently reduced to such a state of anemia and weakness, that effusion may take place in the serous cavities, or, what is more serious, the inflammation gradually returns as the strength improves, and that when his

extreme weakness precludes our having recourse to the remedy we have already employed.

When the patient is strong and robust, I often bleed *coup sur coup*, that is, night and morning for several consecutive days, and, at the same time, apply leeches behind the ears in the middle of the day; but I do not make it a general rule to act in this manner. Sometimes I bleed with the lancet one day, and only apply leeches the following morning; indeed, I am guided by circumstances, and the individual state of the person I am treating. The inflammation is always favourably modified by this plan of treatment, sometimes, even, it is entirely subdued; the vascularization of the sclerótica, as also that of the conjunctiva, disappearing, and the cornea recovering its usual transparency. In some cases, however, bleeding alone will not completely subdue the disease.

Some practitioners advise blood to be taken from the foot sooner than from the arm, because they think that blood-letting thus practised exercises a derivative action. As, however, I cannot understand why the effect of venesection performed on the veins of the foot should be more derivative than when performed on those of the arm, I shall not say any thing further on the subject.

Local blood-letting is often associated with general blood-letting, but it is also frequently resorted to alone, when the latter mode of depletion is inapplicable, owing to the state of anemia in which we find the patient. In these cases the local abstraction of blood will produce the same effect on the inflamed membrane, and that without much loss to the economy. When leeches are employed, they may be applied either on the mastoid region, on the temples, or round the orbits. My own experience has not shewn me that they are more useful in one region than in another; nor do I think that the question can easily be solved, as the efficacy of leeches is not, in the majority of cases, sufficiently evident to enable us to form a correct estimate of the benefit that has been derived from their use. In my opinion, therefore, it is of but little importance which of the regions I have named is selected, unless it be in private practice, when it is as well not to place them round the orbit, as the swelling of the eyelids to which they give rise often alarms the patient and his family. The tumefaction being merely due to serous or sanguineous infiltration, and nearly always disappearing in the course of two or three days, there is no real foundation for the fears which are entertained. I am, indeed, inclined to believe that, acting as a revulsive, it may favour the resolution of the

malady. It is, nevertheless, better for the surgeon not to have recourse to a plan of treatment which may create a disagreeable impression on the mind of his patient. Leeches may also be placed, as in keratitis, on the internal surface of the eyelids, where two or three will often exercise as great an influence over the disease as fifteen or twenty applied on another region. But this is a practice which I only follow when I wish to act on the inflammatory affection of the iris, with the loss to the system of as little blood as possible.

Cupping, which is preferred by some practitioners to every other kind of local depletion, may be resorted to under the same circumstances as leeches, the indication for the one being also the indication for the other. Many surgeons think that advantage is to be derived from cupping in one region sooner than in another, but I have not, in my own practice, found this to be the case.

When the inflammation persists, after general and local blood-letting have been employed, other remedies must be tried, the most important of which are purgatives.

*Purgatives* have always been much employed in the treatment of acute iritis. You know I look upon them as irritants which act by depriving the economy of a certain proportion of its elements. Weller extols the purgatives that are in general use, such as senna, jalap, gamboge, &c. but without appearing to entertain any peculiar theoretical ideas respecting their mode of action. Other surgeons, attributing to this class of therapeutic agents specific properties, employ the drastic purgatives, such as aloes, scammony, &c. in frequently-repeated doses, with a view to irritate the intestinal canal. English practitioners, guided by the theoretical ideas which they profess, make frequent use of purgatives. In France, a short time ago, purgatives were generally accounted irritants capable of inflaming the intestinal canal unless administered with the greatest precaution. With our friends on the other side of the channel, no such fears existing, they are constantly resorted to: calomel, either alone or associated with some other substance, is the purgative they most frequently employ. Nor can we be surprised at this, when we recollect that calomel is considered by them not only to be an excellent antiphlogistic, but also to possess properties peculiar to itself, and is, consequently, generally introduced into their prescriptions when they consider purgatives indicated.

Calomel is employed in England as a purgative, with a view to produce mercurial action, and as an alterative. When given as a purgative, the dose is from two

to six grains, repeated for several consecutive days. When given in order to produce salivation, ten, fifteen, or twenty grains, are administered every day in divided doses; and lastly, when it is thought desirable to produce an alterative effect, it is employed in small doses, combined with opium or hyoscyamus, two or three times a day. Calomel has been used in the same manner in France; indeed, some of our countrymen have even gone farther than the English surgeons. A medical gentleman of Avignon, for instance, having made a journey to England, became convinced that calomel was a heroic remedy against acute iritis, and determined on his return to give it a trial. This he did in the Hospital of Avignon, where he gave, with great success, it appears, as much as twenty and thirty grains of calomel daily to his patients. I have myself given every species of purgative, and that in every possible manner, and have come to the following conclusions:—Ordinary purgatives, whether they act as evacuates or as irritants, have never appeared to me to possess much efficacy in the treatment of iritis. I have never seen the inflammation disappear in such a manner as to leave me the conviction that it was to the purgatives I had administered that its disappearance was due. I have very frequently given calomel, both as a purgative, as a mercurial agent, and as an alterative, and I must say that I have sometimes seen the iritis disappear when the economy was deeply disturbed by its action. Thus I have seen the decrease and final disappearance of the inflammation coincide with salivation, but I am not prepared to say whether this was the result of the medication I was employing, or whether it was mere coincidence. We had a few days since, in our female ward, a woman labouring under iritis, accompanied by chronic keratitis. Blood-letting and topical remedies having proved unavailing, I gave her ten or twelve grains of calomel every day for five successive days. The calomel caused violent purging, as also salivation, and the intensity of the iritis was, at the same time, much mitigated. This at first appears conclusive as regards the efficacy of calomel; but if we scrutinize narrowly the facts of the case, we shall find that we are not in reality authorised to draw from it such an inference. While she was taking the calomel a blister was placed on the calf of each leg, and the application of one of these blisters was followed by severe phlegmonous erysipelas. We cannot, therefore, but ask whether the amelioration which took place is to be attributed to the salivation, or to the revulsive action set up on the leg. But this is a question which I

do not feel able to answer, as I have seen in many other instances salivation productive of no benefit whatever. In fine, I believe that calomel, given in large doses, may prove useful in the treatment of acute iritis; but, on the other hand, I doubt whether the accidents to which the presence of this substance in the economy often gives rise, are not of such a nature as to more than counterbalance the benefit which may be derived from it. It is well known that salivation is sometimes followed by a form of diarrhœa which is extremely difficult to cure, as it depends on a serious lesion of the intestinal canal. In several cases of this kind which I have been able to examine after death, I have found the mucous membrane of that organ tumefied, of a greyish colour, and disorganized to a surprising extent. Knowing, therefore, that the use of calomel exposes his patient to such an affection, a surgeon must have extreme confidence in its efficacy as a remedy against the disease to employ it in every case—a confidence, indeed, which I am very far from possessing. I often give, however, four, eight, or ten grains, for the first day or two of the treatment.

Tincture of colchicum and oil of turpentine have been lauded by some practitioners as extremely efficacious remedies. Tincture of colchicum has been more especially recommended by M. Carron du Villards, and that principally against the specific forms of ophthalmia. I have often employed this preparation, but do not remember ever having seen the patients on whom I tried it derive much benefit from its use. The action of tincture of colchicum is in my opinion similar to that of other purgatives, and as it is a purgative on which no reliance can be placed, I do not think it will ever be much used in the treatment of iritis. Some English surgeons seem to look upon oil of turpentine as a remedy endowed with extraordinary properties. Thus Mr. Carmichael says he has used it with surprising success in iritis. He gives two, four, six, or even eight drachms, in the twenty-four hours. Messrs. Guthrie, Riggs, Mackenzie, and others, have also published cases which would tend to prove that oil of turpentine is a valuable therapeutic agent in the treatment of iritis. My own experience of the remedy is too slight to enable me to say much on the subject, but on examining the statements to which I have just alluded, I do not find that they are at all conclusive. The patients whose cases are related had all been affected three weeks, a month, or even two months, previous to being treated, and were then either cured in ten or fifteen days, or otherwise the eye became disorganized. But this is what

we see continually when recourse is had to those remedies only which are usually employed. The oil of turpentine is, like the oil of colocynth, an acrid irritating purgative, and its use is not unattended with danger to the intestinal canal. In none of the cases which have hitherto been published do I see any thing which can warrant our preferring it either to calomel or to the other purgatives which are generally used. It is, moreover, a most detestable remedy to take, and why should we choose it, when there are so many of the same nature more agreeable to the patient, and to those who surround him, and also more efficacious?

In addition to blood-letting and purgatives, there are many other general remedies which have been lauded as specifics against iritis. Such are the antimonials, the golden sulphuret of antimony, sulphur, iodine, sudorifics, &c.

I have frequently given tartarised antimony either diluted or in sorbian doses, but have never seen it exercise much influence over the course of the disease. Sometimes, however, when the iritis was already in a great measure subdued, it has appeared to accelerate the resolution of the inflammation. With regard to the golden sulphuret of antimony, it may be classed along with the nitrate of bismuth, which, although extolled for some time as an extremely efficacious remedy, is now looked upon as an inert powder. The same cannot altogether be said of sulphur and iodine. Yet I have given sulphur in doses varying from fifteen to twenty grains, without obtaining any satisfactory results. The utility of iodine is also very questionable, unless it be given, as indeed it generally is, with a view to act on a scrofulous constitution: by improving the general health it certainly will act indirectly on the eyes. The sulphate of quinine is also only useful when the patient is weak and feeble, and can merely benefit the eyes by benefiting the constitution in general.

From the cursory survey we have taken of the various remedial agents which are employed in the general treatment of acute iritis, you will perceive that, with the exception of blood-letting, we have but very little to boast of; that there is indeed no other general remedy on which any dependence can be placed. Such a conclusion is not very flattering to our vanity, but I do not hesitate to make it known to you, as it is the result of my lengthened experience of the disease. It is, in my opinion, much preferable that we should be aware of our ignorance, on a subject with which we really are not acquainted, than that we should delude ourselves with the idea that we are perfectly conversant with it, as in the first case we continue our re-

searches, whereas in the second we remain inactive.

There are a certain number of remedies, such as blisters, setons, moxas, &c. which partially deserve the name of general agents, and which ought, therefore, to be studied before we begin to examine the local treatment of the disease. Applied at the nape of the neck, and in the immediate vicinity of the head, blisters do not appear to exercise much influence over the progress of acute iritis, and as they may act on the lymphatic system, I think it is better not to employ them in those regions. In other parts of the body they may be beneficial; I occasionally apply them on the thighs, or on the calf of the legs, keeping them open for some time. I have in several instances surrounded the neck or the two arms of a patient with a large blister, but have never found the iritis to be sensibly modified by such a measure. In some cases of acute iritis I have applied blisters over the orbit, and this practice has been attended with so much benefit to the patients with whom I adopted it, that I feel inclined to give it a further trial. I have, as you all know, often followed this plan of treatment in the various inflammatory affections of the eye, and have never found reason to repent having so done.

Some authors have spoken of a remedy similar in its mode of action to caustic plaster, as if the effects it produces were quite miraculous. A piece of linen is steeped in an infusion of mezereum root in strong acetic acid, and then applied to the skin, on which it produces vesication, exactly in the same manner as boiling water, or an ordinary blister. I cannot, however, understand why, the effects of these agents being identical, one should be so much more efficacious than the other.

Setons and moxas are also used in the treatment of iritis. They may be useful, but more so in the chronic than in the acute stage of the disease.

## OBSERVATIONS ON PUS, BY HERBERT MAYO, F.R.S.

AN ABSTRACT OF A PART OF A SURGICAL  
LECTURE.—Oct. 1839.

[For the *London Medical Gazette*.]

IN my *Outlines of Pathology*, 1839, I adopted M. Gendrin's statement, that on a suppurating wound of the web of a frog's foot he had seen the blood particles, as they approached the wound, lose their colour, and finally escape from the capillaries as pus particles.

In the fourth edition of my *Outlines of Physiology*, 1837, I mentioned that I had measured the size of the pus particles, which I found to have a diameter of 1-2000th of an inch, and that they appeared to me of the shape of the blood particles.

Recent observations have led me to doubt M. Gendrin's statement, and to recognize my own account of the shape of the pus particles to be erroneous.

The interesting researches of M. Gulliver, which went to shew that in several diseases pus appears spontaneously in the blood, have led, at the same time, to the determination of the true figure of the pus globule.

The following are a few observations relating to these subjects, which I have made in preparation for this lecture, availing myself of a microscope, made by Powell, belonging to Mr. Tomes, senior house-surgeon of the Middlesex Hospital:—

1. Pus particles are globular; they are often, however, irregular in figure, being liable to be flattened by pressure. They seem either to be composed of a uniform transparent substance, in which several nuclei are embedded, or to consist of many cohering granules: sometimes one, sometimes the other, character predominates. The edge is never exactly even, but appears slightly granulated. The globules may be seen to roll over in the liquid in which they float, rendering their figure determinable with accuracy. They are brittle; so that half a pus globule is sometimes seen with an irregular broken surface. As the fragment of the broken globule retains its shape, that of a portion of a sphere, it is evident that the globule is not originally a mere vesicle containing detached granules.

2. The size of pus globules obtained from surfaces actively secreting healthy pus, is very uniform. Their average diameter is that which I before gave—namely, 1-2000th of an inch. Under some circumstances, smaller particles, but of a similar structure and shape with those described, are met with in great abundance, mixed with what seem pus globules of the full size. The smallest of these which I have seen, measured 1-5000th of an inch in diameter. When these have been seen by me, I have likewise seen particles of every intermediate size between these and the larger particles mixed with them.

Globules similar to the smaller globules here described are occasionally seen in the blood of healthy persons, together with the larger ones.

3. A suppurating surface in full activity secretes full-sized pus globules alone; and particles of the same size, and of that alone, are found in the blood which escapes on puncturing with a needle the red and inflamed skin immediately surrounding the ulcer. The pus from an issue in a lad, 15 years of age, contained full-sized pus particles alone. Blood obtained by pricking the adjacent red and inflamed skin contained globules resembling pus globules of the same size only.

Matter taken from an ulcer on the ankle of a young man affected with scrofula, contained ordinary pus globules about 1-2000th of an inch in diameter. In blood obtained by pricking the red skin round the same ulcer, granular spherical bodies, of the size of pus particles, as in the last instance, were seen, but apparently in greater numbers than in the blood of healthy persons.

Matter taken from a phlegmonous abscess in the axilla, which had been opened the same day, contained pus globules, of which more than nine-tenths were about 1-2000th of an inch in diameter; there were several larger; some were 1-1200th of an inch in diameter; a few, the largest, 1-900th only. The larger ones were darker and more opaque, but had the same granular structure. One would conjecture that they grow by the aggregation of new granules to their surface. Blood obtained by pricking with a needle the red skin over the abscess, contained, as in the two last cases, globules resembling pus globules found in healthy blood, and not more numerous than in many specimens of healthy blood.

4. Average-sized pus globules, or, at all events, spherical, granular, colourless particles, of about 1-2000th of an inch in diameter, are to be found all but universally in the blood of persons in perfect health. I have examined blood from two boys, from five young men, a few days from the country and in perfect health, from various young and middle-aged persons, residents in London, and from an old woman, aged 63. In the blood of all these persons such globules were to be seen; they were rather more numerous

in some than in others. The only person in whose blood I have not found particles of this description was an aged woman of 77. These globules I suppose to be pus globules, and conjecture to be the same with those to which Mr. Gulliver's observations refer: nevertheless, they differ, to a certain extent, from the globules which are seen in pus from an ulcerated surface. They seem to have less substance, being more transparent; so that I should have hesitated to consider these pus globules, if it were not for the facts to be mentioned in paragraph 5.

5. The circumstances under which I have met with the smaller spherical transparent granular particles, are the following:—In each of two different patients, I punctured with a needle the red skin over an inflamed gland, which threatened to suppurate, but eventually did not. The fluid which escaped contained, besides blood particles, an infinite number of granular, transparent, spherical particles, most of which were about 1-2000th of an inch in diameter, the smallest 1-5000th, mixed with many of every intervening size. On puncturing with a needle the red edge of a rapidly-healing sore on the back of the thigh, the same appearances were met with, as well as in the secretion from the surface of the ulcer itself. In these three cases the fluid which escaped on puncturing the red skin, was at one time as dark as blood, at another was transparent, at another intermediate. The predominance of a red colour was, of course, owing to the presence of more blood and more blood particles.

These observations presented nothing that enables me to form a satisfactory conjecture as to the derivation of pus globules from any of the other elements microscopically visible in the blood. The shape and structure of the pus globule are so dissimilar to that of blood particles, as to make it difficult to imagine the conversion of the latter into the former; nor does it appear much more likely that they are formed by aggregations of the small and apparently spherical and homogeneous particles less than 1-10,000th of an inch in diameter, which are seen, in greater or less numbers, in blood. These, indeed, in blood out of the vessels, have a disposition to aggregation (as the red blood particles have), collecting in granular masses, some of which approach

the circular figure. But they mostly may be seen to group in other figures, of all shapes and sizes, indeed; and where, as it occasionally happens, they come together in a figure nearly circular, the little conglomerate wants the clean and defined outline of the true pus particle.

The pus examined on the occasions mentioned, was taken by applying a piece of glass to a surface covered with pus; over the pus so taken, another thinner piece of glass was laid. The blood examined was taken in a similar way from the drop exuding upon pricking the skin. In two or three instances, a drop of water was mixed with the blood, which rendered the supposed pus globules more distinct, by separating and partly dissolving the blood particles.

The preceding observations have an important bearing on those of Mr. Gulliver. To establish his most interesting views, it is obvious either that he must further shew that the pus globules of *his* observations are not the same with the transparent globules of the size of pus globules, which I have ascertained are all but uniformly, if not uniformly, present in healthy blood; or admitting the identity of the two, he must shew these globules to be more numerous in the blood of persons affected with suppurative fevers than in the blood of healthy persons.

---

#### ON SOME POINTS CONNECTED WITH VACCINATION.

---

*To the Editor of the Medical Gazette.*

SIR,

My attention has lately been called by several professional friends to the "Report on the Present State of Vaccination," drawn up by Dr. Baron, and published under the high authority of the Provincial Medical and Surgical Association. It is a matter of much regret to me, that with many parts of that report I am unable to concur. Circumstances may arise which may induce me to request permission to state, in the pages of your journal, what are the points of doctrine on which I differ with the learned chairman of the vaccination section, the author of the report, and what are the grounds on which my adverse opinions are based. In the pre-

sent communication, I confine myself to one point only; but that one is of great pathological importance.

Throughout the whole of Dr. Baron's report much stress is laid on the frequency with which small-pox *recurs*; and it is argued, that if one attack of undoubted small-pox does not secure the constitution from further assaults of the enemy, no surprise need be felt at the occasional failures of cow-pox. Dr. Baron states (page 66), that 62 correspondents gave returns of 239 cases of recurrent small-pox, of whom 12 or 13 proved fatal. He quotes the experience of Mr. Goolden, who has seen 80 or 90 cases of small-pox after small-pox, many of which were confluent and very severe. He even knew of small-pox occurring a *third* time in two families.

In further support of this opinion, Dr. Baron brings forward (page 64) the following statement:—"In Norwich, we learn from Mr. Cross, that out of 603 persons affected by that disease, 297 had previously had small-pox, 91 had been vaccinated, and that 200 had neither had cow-pox nor small-pox. Of this latter number 45 perished. Of the 91 vaccinated persons, all, with the exception of 2, had a mild affection. *The same seems to have been the case with the 297 who had previously had small-pox.*"

The statement that out of 603 cases of small-pox, 297, or nearly one-half, had previously had small-pox, astounded me not a little, considering that, at the Small-pox Hospital, a twelvemonth often elapses without a case of the kind. I was the more astonished, too, as I had often read Mr. Cross's admirable work, and had no remembrance of such a passage. On reference to Mr. Cross's book (*History of the Variolous Epidemic of Norwich, in the year 1819*), page 7, my wonder ceased. The 603 persons therein named were not persons who had undergone small-pox, but individuals comprising the 112 families in which small-pox had appeared. Instead of finding that, of the 91 vaccinated persons, all, with the exception of two, had a mild affection, I learned (page 36) that two only had had small-pox, and 89 were *unattacked*, though living in the same room with those suffering from small-pox. Lastly, I ascertained that, instead of the 297 persons having

had the disease a second time, they (together with the remaining 15, making 312 in all) "*had no eruptive disease of any sort during the epidemic.*"

I am wholly unable to explain by what inadvertence this error crept into Dr. Baron's report; but it seemed to me very necessary that such error should be pointed out, more particularly as a degree of importance is attached to the principle which it was calculated to support, far beyond that which, in my judgment, a sound pathology would warrant.

I have the honour to be, &c.

GEORGE GREGORY.

31, Weymouth Street,  
Oct. 8, 1839.

## A BEAD TWENTY YEARS IN THE EAR.

*To the Editor of the Medical Gazette.*

SIR,

I SEND you the particulars of a case occurring in my practice, which, as it is rather curious, you will perhaps deem worthy of insertion in your journal.

A few days ago I attended a lady in her confinement with her first child. When 18 months old a glass bead had slipped into her ear; medical advice was resorted to, but the bead could not be extracted, and in the course of time was forgotten. The labour was severe; the efforts of parturition were violent; a slight pain was felt in the ear; and a small body was extruded from it, which on examining, and removing the extraneous matter which surrounded it, proved to be a blue bead of the diameter of the fifth of an inch, and was immediately recognised by the patient's mother as the bead, which, more than twenty years ago, had caused so much anxiety.

The case I regard as curious, and illustrating the extreme violence with which the air, during parturition, must have been forced towards the ear along the Eustachian tube.—I am, sir,

Your obedient servant,

J. DOUGLAS.

14, North Audley Street,  
Oct. 9th, 1839.

## ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

*A Treatise on the Diseases of the Heart and Great Vessels, and on the Affections which may be mistaken for them, &c.* By J. HOPE, M.D. F.R.S. &c. Third edition. London. 8vo. pp. 639.

IN the present edition of this valuable treatise, the author has adhered to the general arrangement adopted in the last, but has made large and important additions to almost every part of it.

The work is too well known and appreciated to require either analysis or encomium; we shall, therefore, only offer a general notice of its contents, with a view to such comments on the new matter as our limits will admit.

In Part I. on the “anatomy and physiology of the heart,” there is a full and unavoidably controversial view of opinions on the causes of the cardiac sounds, with details of all the experiments by which the author has been led to the conclusions in which he now abides. These conclusions we state nearly in his own words.

*First sound.*—This is compound, consisting, first, of the click of the auricular valves; secondly, of the sound of muscular extension—a loud smart sound produced by the sudden extension of the braced muscular walls at the moment when the auricular valves close; thirdly, of a prolongation, and possibly an augmentation, by *bruit musculaire*, or the dull rumbling sound of ordinary muscular contraction. The valvular click gives smartness and intensity to the commencement of the first sound; and in feeble hearts, in which the sound of extension and the *bruit musculaire* are absent, the click alone is heard, making the first sound identical in quality with the second. This occurs, for example, in dilatation with attenuation. The sound of muscular extension adds bluntness and loudness to the valvular click, and is probably a principal cause of the extraordinary intensity of the first sound, often observed in violent palpitation. It differs from the sound of costal percussion with metallic *cliquettes*, which imparts a double character to the first sound, and only exists under particular circumstances. The *bruit musculaire* forms a gradually diminishing prolon-

gation of the sound to the end of the act of contraction; but when the heart acts feebly, either from disease, or from temporary exhaustion or faintness, the *bruit musculaire* may be partially or wholly absent.

*Second sound.*—This results from the sudden expansion of the semilunar valves, occasioned by the reflux of the columns of blood in the aorta and pulmonary artery during the ventricular diastole. The auricles do not contribute to the production of either of the sounds, since, in the experiments on the ass, they were heard in equal perfection when the auricles were motionless. Nor does the auricular contraction, in the author's opinion, occasion any sound whatever; for the movement during tranquil action of the heart, in large animals at least, is too inconsiderable, nor are there any circumstances of structure or resistance to cause valvular or muscular extension. Finally, no third sound of the heart is ever heard.

Here also will be found a very elaborate exposition of the subject of valvular murmurs. The remarks on murmurs from *regurgitation*—the existence of which was first detected by our author—are worthy of particular attention; we can only find space, however, for the following general conclusions on the stethoscopic signs of disease of the cardiac orifices:—

1. The ventricular *systolic* currents through contracted orifices, from being stronger than the *diastolic*, produce louder murmurs.

2. Considerable contractions of a rough, salient configuration, whether osseous or not, produce the rough murmurs of sawing, filing, or rasping, provided the current be that of the ventricular systole, its diastolic currents being too feeble. It has been a prevalent notion, derived from Laennec, and supported by Bertin and Bouillaud, that the sounds indicative of valvular disease were determined, as to their asperity, by the degree of roughness of the obstructing surface, and hence that the bellows sound was connected with fibrous and cartilaginous disease, and those of a rougher character with ossification. Dr. Elliotson believes that the degree of contraction of the orifices is the sole cause of roughness in the sound. Without denying that the degree of contraction is an important modifying cause, Dr. Hope dissents from both the fore-

going opinions, because he has known ossifications, when not very prominent, and especially when covered by the lining membrane of the heart, produce a very smooth bellows sound, and the saw, file, or even the rasp sound, occasioned by fibrous or fibro-cartilaginous disease; and he has further observed that the highest possible degrees of contraction are invariably attended with a soft bellows murmur. He is hence led to conclude that the roughness of the sound is neither connected with the anatomical character of the valvular disease, nor directly proportionate to the degree of contraction; but that it depends on such accidental configuration of the contracted orifice as is most calculated to break the stream of the blood, and to excite large vibrations in it and the adjoining solids.

3. The pitch, or key of murmurs, is higher in proportion as they are generated nearer the surface, and as the currents producing them are stronger; and *vice versa*. The key also is lowered by distance, independently of depth, on account of reverberation through the chest. Thus murmurs seated in the pulmonary orifice or artery, are higher in their key than others, from being more superficial, and those originating in the ascending aorta, where it approaches near the sternum, are almost as high a key; those in the aortic orifice, being rather more deeply seated, are somewhat graver; those of the mitral valve are the lowest toned of all; and those of the tricuspid rather higher than of the mitral, because it is not quite so deeply seated. On the same principle—that the gravity of the sound is increased by remoteness and reverberation—a murmur is low toned, not only from being deeply seated with respect to the parietes of the thorax, but also from being explored at a distance. Thus a murmur seated in the semilunar valves, if explored above the clavicle, or an inch on either side the sternum, or near the apex of the heart, has a graver sound than if explored immediately over the diseased valves. The principal use of this knowledge of the pitch or key of murmurs, is to enable the auscultator to trace the sound to its source, which is at the point where it is loudest and seems nearest to the ear. Dr. Hope says that a student well taught on three or four marked cases, may make himself master of these distinctions in half an

hour. This remark we think will not apply to all ears; for there is great diversity, not only in the acuteness of audition, but in the power of appreciating different kinds of sound: the musical ear, for example, bears no equal ratio to the perfection of the general sense of hearing; and there is much reason to believe that some particular portion of the auditory apparatus ministers especially to the distinction of musical notes.

4. Musical murmurs indicate nothing more than ordinary murmurs.

5. Rough murmurs, and even loud and permanent bellows murmurs, indicate organic disease. This rule we should be disposed to admit only as a very general one, subject to many exceptions; for it is a prevalent, and we believe a correct, opinion, that any of these sounds, when sometimes present, and at others absent, may originate in mere functional disorder; nor can it be denied, on the other hand, that even the roughest sounds, connected with ossification of the valves, do occasionally intermit, owing to causes not easily understood: we doubt, therefore, whether any of the sounds in question can be received as *certain* indications of organic disease, independently of the symptoms; conjoined with these, however, they become perfectly unequivocal.

6. Murmurs from regurgitation necessarily indicate organic disease.

In the section “on venous or continuous murmurs, hum, and musical notes,” our author contends that Laennec, Bouillaud, and others, have been mistaken as to the seat of these sounds; and that the opinion of Dr. Ward, of Birmingham, which refers them to the veins, is correct. According to Dr. Hope’s observations, the venous murmur is in a much lower key than the arterial bellows sound, and where the two strike the ear simultaneously, the arterial may be heard *through* the venous. When there is no considerable arterial throbbing, the venous murmur is equable; but when the arterial throb is considerable, it undergoes augmentations synchronous with the pulsations of the arteries, and consisting in the super-addition of the arterial whiff to the venous murmur. For the grounds of this opinion, and for a minute investigation of the varieties of venous murmur, we must refer the reader to Dr. Hope’s work.

The above-mentioned views have led

our author to a new theory of the utero-placental sound. In a chapter on the application of auscultation to the diagnosis of pregnancy, he expresses his belief that the ideas hitherto prevalent are all erroneous; that Kergaradec, Kennedy, P. Dubois, &c. are mistaken in restricting this sound to the uterus, placenta, or both; that Bonillaud errs equally in restricting it to the great arteries of the pelvis; and that all are wrong in attributing it to the arteries exclusively of the veins.

Dr. Hope submits the following propositions for further investigation:—

“1. That the murmur is arterial when it is a whiff.

2. That it is venous when continuous without augmentations synchronous with the pulse.

3. That it is arterial and venous conjoined when it is continuous with augmentations.

4. That its seat is sometimes in the vessels of the abdominal parietes, as the epigastric, circumflexed ilii, internal mammary, and their branches and concomitant veins; sometimes in the great arteries and veins within the cavity of the abdomen, as the common and external iliacs, the renal, the three branches of the cœliac, the colica dextra, media, sinistra, and ileo-colica, and the portal veins; sometimes, possibly, in the uterine walls, and sometimes, possibly, in the vessels of various tumors.

5. That the murmur is generally created by pressure, whether that of the uterine or other tumor or of the stethoscope; and that it does not exist independent of pressure except, possibly, in anæmic cases.

6. That the stretched condition of the arteries, and especially the veins of the abdomen, is favourable to the operation of pressure in producing the murmur.”

He goes on to show, that the reputed utero-placental murmur is in all respects analogous to that heard in the neck of anæmic subjects. It is sometimes an arterial whiff, as in the carotids; sometimes continuous, with augmentations, as in the carotids and internal jugulars; sometimes continuous, with little or no augmentation, as in the jugulars; sometimes whistling, and sometimes ceasing, without assignable cause, as in the jugulars; lastly, it is most marked in anæmic subjects.

These positions, which are illustrated by a series of cases, are advanced by Dr. Hope only as subject to addition or

correction. Meanwhile he draws from them the following practical conclusions:—

“1. A near-sounding, high-toned, continuous, or venous murmur, with arterial augmentations, heard opposite to the anterior superior spinous process of the ilium and a little above, does not necessarily indicate pregnancy, because it may exist in connection with other tumors, and also wholly independent of any tumor. It occurs almost exclusively in the thin-blooded, or anæmic with a quick pulse.

2. An obscure, distant, low-toned murmur, synchronous with the pulse and not continuous, though sometimes rather prolonged, heard on a tumor in the hypogastric region, affords presumptions that the tumor compresses the iliac vessels.

3. When either or both of the murmurs coincide with other symptoms of pregnancy, they afford presumptions of this state, but do not warrant an affirmation.”

Part II., on the “inflammatory affections of the heart and great vessels,” is much extended from the last edition, and contains an immense mass of pathological and practical information. The section on pericarditis is particularly valuable. Difficult of detection as this disease unquestionably is, in its obscurer forms, we think that the practitioner who carefully reads and applies Dr. Hope's observations can hardly err in his diagnosis. The subject of *endocarditis*, or inflammation of the lining membrane of the heart, is also treated with great ability. The diagnosis of this from pericarditis must be acknowledged to be still very imperfect, and the difficulty is much increased by the frequent coincidence of the two affections. Dr. Hope thinks that endocarditis is more apt to occur separately than pericarditis. He sums up his view of the general and physical signs of endocarditis by stating, that it may be anticipated on the sudden supervention of the following symptoms:—1. Fever. 2. Violent action of the heart. 3. A valvular murmur which did not previously exist—provided the murmur be well distinguished from that of attrition, which indicates pericarditis. The evidence will be still stronger if these signs occur in connection with acute rheumatism. The mention of the last-named disease reminds us to direct the attention of our readers to a remark of Dr. Hope's

on what is called the *metastasis* of rheumatism to the heart and other internal organs. This has been considered, as the name implies, to be a total change of place, and transference of the morbid action from the external to the internal parts. Our author believes that this is altogether a mistaken notion, and regards the so-called metastasis as merely an extension of the inflammation to the internal fibrous tissues, precisely similar to its migration from the fibrous tissue of one joint to that of another. He declares that he has not only seen, in a great number of cases, the heart attacked while the rheumatism existed in full intensity in the joints, but has also seen the heart invaded before the joints; and that he knows other practitioners who have witnessed the same. The former of these occurrences has repeatedly fallen under our own notice; and we should indeed be further inclined to maintain that there is considerable functional derangement of the heart in almost every case of well-marked rheumatic fever. We infer this from the intense action of the heart; from the hard and vibratory character of the pulse, which are usually much more than commensurate with the other symptoms of inflammatory excitement throughout the system; and from the entire inefficacy of blood-letting in permanently reducing this state of the pulse.

Part III. on the "organic affections of the heart and great vessels," comprises the structural diseases of the muscular substance—of the pericardium—of the internal membrane and valves—and of the aorta. Independently of the excellence of this portion of the work as an exposition of the anatomy and semiology of the organic lesions of the heart and great vessels, we consider it especially valuable as placing the pathology of the heart in apposition with that of other organs, and pointing out the great influence of its diseases on the cerebral and pulmonary circulation. Though we are indebted to the French writers for the first distinct announcement of these facts, Dr. Hope has kept them more constantly in view, and illustrated them more amply, than any other author.

The following statement of thirty-nine cases, which occurred in the course of two years in the St. Marylebone Infirmary, affords a remarkable illustration of the connection between disease of the heart and cerebral apoplexy:—

"Of the 39 cases, 4 died of apoplexy between birth and 40; 9, between 40 and 50; 6, between 50 and 60; 7, between 60 and 70; 11, between 70 and 80; 1, between 80 and 90; and 1, between 90 and 100.

Hence it would appear, that the periods of life during which fatal apoplexy is most prevalent are between 40 and 50, and between 70 and 80.

We have now to examine in what proportion of these cases disease of the heart existed.

"In 4 out of the 39, the heart was found 'quite healthy.' In 8 cases more, no remark is made in the journals as to its condition; it may therefore be presumed to have been healthy. This affords a total of 12 cases out of 39, in which the heart was sound: in the remaining 27, it was diseased.

Thus, taking all the ages collectively, disease of the heart accompanied fatal apoplexy in no less than 27 out of 39—*i. e.* 9-13ths, or nearly three-fourths.

We will now examine at which of the above periods of life disease of the heart, in connection with fatal apoplexy, was most prevalent.

Between *birth* and 40, disease of the heart was not found in any of the 4 fatal cases that occurred within those dates. Between 40 and 50, it occurred in 8 out of 9!—a remarkable increase. Between 50 and 60, it occurred in 4 out of 6,—a decrease. Between 60 and 70, it occurred in 3 out of 7—a further decrease; and between 70 and 80, it occurred in 10 out of 11!—another remarkable increase.

It would thus appear that the periods of life during which fatal apoplexy is most prevalent, are precisely those in which concomitant disease of the heart is of most frequent occurrence; namely, between 40 and 50, and between 70 and 80.

It was stated above, that, taking all ages together, disease of the heart occurred in 9 cases out of 13, or nearly  $\frac{3}{4}$ , of fatal apoplexy. Now this proportion is, I apprehend, *much* greater than is generally imagined or believed; and it sufficiently evinces the importance, in medical practice, of carefully studying how far the state of the heart and that of the brain may be allied as cause and effect.

But, in the two apoplectic periods of life, if I may be allowed the expression, *viz.* between 40 and 50, and between 70 and 80, the proportion is much greater;

for, instead of being 9 out of 13, it is in the proportion of 9 out of 10, and 10 out of 11. Hence, it is desirable to direct our attention, in the treatment of apoplexy, to these two periods more especially; and, in order to do it with effect, it is necessary to investigate the reasons why fatal apoplexy occurs in connection with disease of the heart, during these periods in particular.

Now, on examining the cases occurring between the ages of 70 and 80, 7 out of 10 present ossification of the heart. On the other hand, between 40 and 50, disease of the *muscular* structure of various kinds prevailed, while ossification was comparatively rare.

Hence it appears deducible, as a generalization, that it is disease of the *muscular* structure more especially which causes apoplexy in the earlier period of its prevalence; and that it is mainly ossification which occasions it in the more advanced period."

In the first edition of this work, our author followed Bertin and Bouillaud in enforcing a relation between pulmonary apoplexy and hypertrophy of the right ventricle, similar to that which obtains between cerebral apoplexy and hypertrophy of the left. He has since found reason to doubt the accuracy of this opinion, which has also been relinquished, or at least reduced to the form of a query, by M. Bouillaud. Larger experience has led our author to conclude that pulmonary apoplexy is more uniformly dependent on great contraction of the mitral valve, with or without hypertrophy and dilatation of the right ventricle, than on any other lesion. This conclusion is corroborated by Dr. Wilson. Dr. Hope adds, that he has lately found softening of the heart a frequent cause of pulmonary apoplexy.

Our author's researches on aneurism of the aorta enriched the pages of this journal prior to the first publication of the work before us. In their present enlarged form they constitute an admirable treatise on this lesion. Dr. Hope adds, in an appendix, a remarkable case in which an aneurism of the aorta burst into the right ventricle of the heart, and another, communicated by Dr. David Monro, of Edinburgh, in which the aneurism burst into the pulmonary artery.

Part IV. on "nervous affections of the heart," comprises neuralgia of the heart or angina pectoris, palpitation, and syn-

cope. This portion of the work has received less addition than the preceding. Among the most diagnostic signs of palpitation from anæmia, the author insists on the venous murmur of the jugular veins, especially the internal. He also represents this phenomenon as an invariable attendant on the inorganic murmurs of the heart and arteries.

Part V. on "miscellaneous affections," also stands nearly unaltered from the last edition, with the exception of some judicious remarks on the treatment of polypus of the heart.

Part VI. consists of illustrative "cases," the number of which is augmented in the present edition: of these we are necessarily obliged to omit all notice. At the end of the volume there is a table of pulses indicative of the diseases of the heart. The author hopes hereafter to show, that such pulses imitate all those produced by ordinary diseases, and consequently, that unless the pulses of heart disease be abstracted, the pulse is but a fallacious guide in other diseases. The ambiguities of nomenclature, and the various nicety of touch in different individuals, have rendered the classification of pulses extremely vague from the days of Galen downwards. Dr. Hope's design, however, is meritorious, and, with reference to the more obvious qualities of the pulse, cannot fail to be useful.

In concluding this brief notice, which is very incommensurate both with the importance of the subject, and the merits of the work, it is almost superfluous to say any thing in the way of recommendation. Dr. Hope's treatise is the most elaborate and complete, and the richest in original observation, that has yet been published on the same subject, and as such it is an indispensable book in every medical library.

—  
*The Surgeon's Vade-mecum; a Handbook of the Principles and Practice of Surgery: illustrated with numerous Wood Engravings.* By ROBERT DRUITT, M.R.C.S.L. H. Renshaw, and J. Churchill, 1839. 12mo. pp. 423.

THERE must be a large body of students and practitioners who very naturally wish to inform themselves of the most recent improvements in surgery, without the trouble of wading through a horde of original treatises, or the thousand-and-one pages of the voluminous

systems and dictionaries of the day. To such persons Mr. Druiitt's hand-book may safely be recommended. It is evidently drawn up with no little labour, and the language is as concise as it can be, without obscurity. The following passage will shew the author's care to include the rarest surgical affection:—

“*HERNIA BRONCHALIS (Bronchalis vera, Goltre aërien)* is a very rare tumor, formed by a protrusion of the mucous membrane through the cartilages of the larynx or the rings of the trachea, and caused by violent exertions of the voice. Lurcy met with sundry instances of it in French officers, and in the priests that call the people to prayer from the tops of the minarets in Mahomedan countries. The tumor is soft and elastic, can be made to disappear by pressure, and is increased by any exertion. The only available treatment is moderate support.”—P. 322.

Altogether Mr. Druiitt's work presents a very useful summary of the present state of surgical science and practice.

## MEDICAL GAZETTE.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”  
CICERO.

### SIR JAMES CLARK'S STATEMENT.

WE have hitherto abstained from making any allusion to the proceedings at Court in reference to the unfortunate case of Lady Flora Hastings; and we adopted this negative course partly because we had no data—at least none of a public nature—to warrant us in expressing our opinion; and partly out of consideration for her medical attendant, for whose situation we felt, and who, by his own studied silence under reiterated provocations, seemed willing that the subject should be allowed to drop. But Sir James Clark having at length come forward, and given what we unhesitatingly receive as an authentic account of his share in the transaction, we find our

position entirely, and, we shall at once admit, rather painfully altered. We do not think that, as public journalists, we should be warranted in any longer declining to discuss a subject which has excited so much attention, and which involves considerations of so much importance both to society at large, and to the medical profession in particular. Putting, then, aside all irrelevant questions, and freed, as we believe ourselves to be, from all participation in those popular and party feelings with which the subject has been mixed up, we shall proceed to consider the question simply as one of medical ethics.

It appears from the narrative of Sir James Clark, that he was consulted by Lady Flora Hastings on the 10th of January, 1839, who at that time laboured under pain low in the left side, with derangement of the bowels and general health. The symptoms thus described gradually yielded to simple remedies, so that after a short period Lady Flora complained only of some remaining weakness. Nevertheless, a considerable enlargement of the abdomen, which had been present throughout, continued undiminished. After Sir James had been about three weeks in attendance, he was sent for by Lord Melbourne, who informed him that it was suspected about the Court that Lady Flora Hastings “might be privately married.” To this her medical attendant stated in reply, that “while he thought such suspicions ought not to be readily listened to, he was at the same time bound to admit, that the appearance of Lady Flora in some degree countenanced them;” adding, “that without more ample means of observation, he would not venture to give an opinion on the subject.” And here, we humbly submit, was Sir James Clark's first mistake. He does not seem to be aware that, under such circumstances, his declining to give an opinion in fa-

your of his patient's innocence amounted to a very strong presumption of her guilt. It is a principle perfectly understood in our profession, that the medical attendant throws himself between his patient and any such gossiping surmise, and defends her reputation to the very last. At all events matters had now come to this pass, that it was Sir James Clark's duty, if he entertained the slightest doubt, immediately to have had the question set at rest, either by instituting the necessary examination himself, or having another person to do so. Instead of this, however, Lord Melbourne's communication led to nothing. Sir James continued to visit his patient as before, contenting himself with occasionally examining the enlargement "over her dress;" till at length being (of course) quite unable to satisfy himself in this way, he one day requested that, at his next visit, he might be permitted "to lay his hand upon her abdomen with her stays removed"—a proposal which Lady Flora refused to comply with. And here we cannot but remark, that there seems to have been a great want of tact in Sir James Clark's mode of proceeding, in thus talking to her about laying his hand upon her abdomen, and having her stays removed; there was a particularity in all this which would have induced many young women to decline the proposal. Females will suffer much to be silently done that they will not submit to if it be talked about, and put prominently before them in words. We believe that if Sir James had contented himself with merely telling Lady Flora that she had better remain in bed next morning till after his visit, he would have had no difficulty in accomplishing his object. However, the matter, it might be supposed, was now brought to a crisis. The lady was suspected of pregnancy; her medical attendant proposed an examination, which he deemed essential, and this was denied him. Of course the

reader will expect to learn that Sir James Clark now declined to take any further responsibility. Not at all; he continued his visits as before till the 16th of February, when he was informed that that which he ought to have done had been determined upon by others—namely, that another physician should be sent for to decide the question of pregnancy. The proposal did not emanate from Sir James; and here is evidently one of the greatest errors of judgment he displayed in the course of this unhappy business. As soon as a suspicion of pregnancy was known to be entertained, the path lay clear before him: instead of fearing the presence of another physician, he ought to have sought for it, and been relieved by the opportunity thus afforded him of declaring that the question was no longer one which fell within his province. His namesake would then have been sent for at his suggestion, instead of being thrust upon him, and, in all probability, the whole of the mischiefs which have since pressed so hard upon him would have been avoided.

The reference to a second opinion having thus been determined upon by others, he proceeded to Lady Flora on the 16th of February, to make her acquainted with this decision, and she at once agreed to see Sir Charles Clarke. Here there occurs in the narrative of Sir James a circumstance which shows how much he deceives himself as to the degree of consideration and forbearance which he supposes himself to have shewn to Lady Flora. He had been six weeks in attendance without proposing that any other person should be called in; but now he abruptly urges her "to see another physician at once"—"to see him on that day"! Did it never strike him as unreasonable to expect that she should, at the instant, accede to what he had been so long in attendance without thinking it necessary to suggest? That she who had recently shrunk from

the examination of her person without her stays, should "at once" bring her mind to the more revolting procedure which he now proposed? She did, indeed, "at once" agree to see Sir C. Clarke; but because she did not consent to send for him on the instant, Sir James informs us that it lessened very considerably the effect produced on his mind by her protestations of innocence—an admission which, in our opinion, savours strongly of a foregone conclusion, and one which probably influenced his deportment to an extent of which he was not himself aware. In fact, it appears from his own showing, that, immediately after his interview with Lady Flora, he expressed his opinion of her guilt to the Duchess of Kent, in no equivocal terms.

An examination was made, as our readers well know, and of the result of which all the world is aware. And this brings us to another point in the "Statement," namely, a direct reference to Sir Charles Clarke—associating him with some not very intelligible expressions connected with the case. We shall quote them. "And if any thing further were required to establish the difficulties of this very peculiar case, and the heavy responsibility attaching to a decision on it, Sir Charles Clarke knows that there are other facts connected with it which prove, in the most unequivocal manner, both the one and the other—facts which do not throw the slightest shade of doubt on the purity of Lady Flora, nor are matter of blame to any one, but which it is not necessary to bring before the public."

Now this would appear to refer to something which passed at the consultation, but not in any manner involving the results which followed. Such being the case, pray what is the purpose of the paragraph—what the object of its introduction here? The most obvious interpretation certainly is, that Sir C. Clarke

had expressed some doubts or misgivings upon the subject, and thus placed himself more nearly than the world imagines in the same position as his namesake. We earnestly trust, however, that we are mistaken in supposing that it relates to any thing which passed in private at the consultation, because we conceive that any such reference is a breach of professional ethics. The opinion by which Sir Charles Clarke was to stand or fall he gave in his certificate, and as regards this question the public has nothing to do with any thing else.

Upon the whole, we think that Sir James Clark was too much under the influence of the scandal-mongers, to protect his patient as he ought to have done; and with his mind imbued with their suspicions, he neither had the prudence to insist upon the necessary examination himself, nor yet the wisdom to have it instituted by another. He was thus placed in a situation of embarrassment, from which, as it appears to us, he was prevented from extricating himself, simply by the wish to avoid suffering any other medical attendant to be employed about the Court.

Such we regard as the sum of his offending; and it is an error which many might have fallen into without suffering nearly so severely as he has done in consequence. Now two circumstances have led to Sir James Clark being visited more severely than another might have been: first, the whole affair has been made a party question, and some of the newspapers have shewn an equal want of candour, moderation, and even of common justice, in the way they have treated him. But again: the extent to which Sir James has suffered is also partly dependent upon some by-gone, but, it would appear, not forgotten conduct of his own:—we refer to the medical appointments to the royal household which were made on the accession of her present Majesty.

At the time alluded to various changes took place. Sir J. Clark's own name was placed first on the list of Court physicians, and the minor appointments were many, if not all of them, known to be more or less influenced by his views and wishes. Some gentlemen who had held medical appointments during the preceding reign, and, we believe, most faithfully discharged their duties, were unceremoniously dismissed—the office of one, we have understood, merging into that held by Sir James himself. The medicines, too, were no longer supplied as before, but furnished by a chemist the protégé—a very meritorious one, but still a new man, and the protégé—of Sir James Clark. Now we do not say that many persons would not have served themselves and their friends in like manner, had they had similar opportunities; but still, whoever adopts this line, must make up his mind, if the day of adversity come, to find many who, if they do not positively rejoice in his misfortunes, at least feel no such sympathy for him as his case would otherwise undoubtedly have excited.

But although we do not think Sir James Clark acted very wisely, yet we are quite sure that the same thing might have occurred, under different circumstances, without any such formidable results as have followed on this occasion. It is the use which has been made of these unfortunate events for party purposes which has rendered them so injurious to the Court physician;—and this ought to be an impressive lesson to all those who are ambitious of such dangerous honours. Another point strongly illustrated by these events is the imprudence of attempting to monopolize royal favours. Had Sir J. Clark not been so apprehensive of a rival near the throne, but had some other of the Court physicians called into consultation; or if, on the first question of pregnancy, he had declared it to be out of his department, and required

that his namesake might be sent for—how different a position would he now have occupied!

As to the pamphlet which has called forth these remarks, (remarks which our long silence will shew that we have been reluctant to make), we cannot see in what manner it can possibly do him any good, and we think Sir James has been ill advised in publishing it. Many supposed that his long and apparently pre-determined silence resulted from deference to some person or personage who would unavoidably become implicated in the disclosures which he had to make. But this idea he has entirely destroyed by his pamphlet—concerning which people will marvel, if he thought it worth publishing at all, why it was not done—at once.

#### SIR JAMES CLARK'S STATEMENT

##### OF THE CASE OF THE

#### LATE LADY FLORA HASTINGS.

So long as the accusations brought against me, in reference to the case of the late Lady Flora Hastings, continued to be either anonymous or unauthorised, I felt it right to submit in silence to every species of provocation, rather than bring before the public circumstances of a very delicate nature, which came within my knowledge in the implied confidence of professional intercourse. The publication, however, of the Marquis of Hastings, the nearest relative of Lady Flora Hastings, made me doubt seriously whether in regard to myself, as well as the profession, I was justified in not laying before the public an account of the case so far as I was concerned. The renewed attacks which have followed that publication permit me no longer to hesitate; although, even now, it is with utmost reluctance I bring myself to enter into details which I am of opinion ought never to have been made the subject of public discussion.

On the 10th of January last I was consulted by Lady Flora Hastings, who had that day arrived from Scotland, and had come into waiting on her Royal Highness the Duchess of Kent. She had derangement of the bowels, and of the general health, and she complained of pain low in the left side. There was also considerable enlargement of the lower part of the abdomen.

Under the use of some very simple

remedies, the derangement of the bowels and the pain in the side gradually abated, and ultimately ceased; and Lady Flora complained only of weakness.

The size of the abdomen, however, continued undiminished, and Lady Flora's appearance became the subject of remark in the palace. About the 1st of February, as nearly as I am able to fix the date, I was sent for by Lord Melbourne; and on going to him, his Lordship informed me that a communication had been made to him by Lady Tavistock, respecting Lady Flora Hastings, whose appearance had given rise to a suspicion in the palace that she must be privately married; his lordship asked my opinion on the subject. I stated, in reply, that while I thought such suspicions ought not to be readily listened to, I was at the same time bound to admit to him that the appearance of Lady Flora in some degree countenanced them. I added that without more ample means of observation, I could not venture to give an opinion on the subject; and his lordship agreed with me that no step should be then taken in the matter.

From this time the condition of Lady Flora Hastings caused me considerable anxiety. The only source, besides pregnancy, from which the size and peculiar form of the abdomen could proceed, was disease, but the probability of disease being the sole cause in Lady Flora's case was diminished by the circumstance that the enlargement was accompanied by very little derangement of health. In fact, Lady Flora continued to perform her usual duties with apparent little inconvenience to herself.

I continued to visit Lady Flora about twice a week, from the 16th of January to the 16th of February, and on several occasions examined the state of the abdomen over her dress; but being unable, in this way, to satisfy myself as to the nature of the enlargement, I at length expressed to her my uneasiness respecting her size, and requested that, at my next visit, I might be permitted to lay my hand upon her abdomen with her stays removed. To this Lady Flora declined to accede.

Matters remained in this state until the 16th of February. On that day I found it had been determined that I should acquaint Lady Flora with the suspicions which existed in the palace, and should suggest her calling another physician into consultation with me. Before visiting Lady Flora, I asked Lady Portman, the lady in waiting, if I might use her name to Lady Flora, as one of the ladies who entertained the suspicion respecting her. To this Lady Portman at once assented. Her Ladyship then described the peculiarities in Lady Flora's form and carriage which had produced the impression in

regard to her state. To the question as to what my opinion on the subject was, I replied that the appearances were certainly suspicious, but that even to medical men such appearances were often deceptive. Lady Portman concluded by observing, that for the sake of Lady Flora Hastings herself as well as of the court, it was necessary that the matter should be cleared up. Immediately after this interview with Lady Portman, I went to Lady Flora for the purpose of making to her this very unpleasant communication; and I need hardly add that I made it in the most delicate terms which I could employ. After a few remarks on the state of her health, I told her that her size had attracted the attention of the ladies, and that it was now my painful duty to acquaint her ladyship that they had in consequence been led to suspect that she must be privately married. This was the mode and these were the words in which the painful communication was made.

I urged Lady Flora, for obvious reasons, if there were grounds for this suspicion, to acknowledge the fact, and if not to see another physician at once, to put an end to the rumour. Lady Flora denied that there were any grounds whatever for the suspicion, and named Sir Charles Clarke, who she said, had known her from her childhood, as the physician she would wish to be called in; but she declined, notwithstanding my earnest entreaties, to see him on that day. This refusal, after the reasons which I had given, lessened very considerably the effect upon my mind of her Ladyship's denial.

After the interview with Lady Flora it remained for me to communicate what had passed to Her Royal Highness the Duchess of Kent. I therefore informed Lady Flora that I was going to Her Royal Highness for that purpose; to the propriety of this Lady Flora immediately assented. I accordingly went to the Duchess of Kent, and stated the nature of the interview I had with Lady Flora. Her Royal Highness immediately expressed her entire disbelief of anything injurious to Lady Flora's character, and she asked me my opinion. However reluctant I felt to express any doubts on the subject after Lady Flora's declaration, I could not decline giving a conscientious reply to Her Royal Highness's question; and I answered to the effect that the suspicions I previously entertained were not removed.

In the course of the evening of the day on which I made the communication to Lady Flora Hastings, I received a note from her Ladyship, of which the following is a copy:

“Saturday.  
“Sir,—Although I think you perfectly understood me this morning, that I did not

wish you to take any steps without hearing from me, it is perhaps better, to obviate the possibility of any mistake, that I should distinctly say so. I shall be governed entirely by Her Royal Highness's wishes and orders.—Yours sincerely,  
 “FLORA ELIZ. HASTINGS.”

I heard nothing more on the subject till the afternoon of the following day, (Sunday, February 17th,) when I received another note from Lady Flora, of which the following is a copy :

“Sir,—By her Royal Highness's command I have written to ask Sir Charles Clarke to name an hour this afternoon to come to me. He has answered my note by coming, and is now here. Could you come and meet him?—Yours sincerely,  
 “F. E. HASTINGS.”

On receiving this note I immediately went to Lady Flora, and found Sir Charles Clarke with her Ladyship. He stated to me, in Lady Flora's presence, as part of the conversation he had had with her, that he urged her, if there were any grounds for the suspicions entertained, to admit the fact now, as after the examination it would be too late.

After this conversation, Lady Flora requested that Lady Portman might be called in. On her arrival, Lady Flora retired to her chamber, where her maid was in attendance. After Sir Charles Clarke had made an examination, he returned with me to the sitting-room, and stated as the result, that there could be no pregnancy; but at the same time he expressed a wish that I also should make an examination. This I at first declined, stating it to be unnecessary; but, on his earnestly urging me to do so, I felt that a further refusal might be construed into a desire to shrink from a share of the responsibility, and I accordingly yielded. After finally consulting, we gave the following certificate.

(Copy of Certificate.)

“Buckingham Palace, Feb. 17th, 1839.

“We have examined with great care the state of Lady Flora Hastings, with a view to determine the existence or non-existence of pregnancy, and it is our opinion, although there is an enlargement of the stomach, that there are no grounds for suspicion that pregnancy does exist or ever did exist.

“CHARLES M. CLARKE, M.D.

“JAMES CLARK, M.D.”

Before parting with Lady Flora both Sir Charles Clarke and myself pressed upon her Ladyship the expediency of her appearing on that day at table as usual.

Such is a plain statement of the lead-

ing facts of this unfortunate case, so far as I am concerned. That I was unable to ascertain the true nature of Lady Flora's state, I at once admit, and most deeply regret: but when the difficulties which frequently occur in cases of this description, even where every facility is afforded for investigation, are considered, it can scarcely be made a matter of reproach to me that, amidst the disadvantages under which I laboured, I was unable to affirm that Lady Flora's change of appearance was the result of disease, and of disease alone. If even Sir Charles Clarke did not venture to express a positive opinion until after a careful examination, it will be readily conceded that no other person could have done so without recurring to some similar proceeding. And if anything further were required to establish the difficulties of this very peculiar case, and the heavy responsibility attaching to a decision on it, Sir Charles Clarke knows that there are other facts connected with it which prove, in the most unequivocal manner, both the one and the other—facts which do not throw the slightest shade of doubt on the purity of Lady Flora, nor are matter of blame to any one, but which it is not necessary to bring before the public.

The *post-mortem* examination established the fact, that the death of Lady Flora Hastings was occasioned by extensive disease, dating its origin “at some former and distant period of time;” and yet such was the obscurity of the symptoms which, during life, accompanied the disease, that its nature became evident a few weeks only before Lady Flora's death; and the fact of its having involved every organ within the abdomen was revealed only by the *post-mortem* examination.

I think it right to notice, in this place a part of my conduct which may at first sight appear censurable. I allude to the admission of my suspicion, that Lady Flora might be pregnant, before I had been permitted more fully to examine into her state. Under almost any other circumstances it would have been highly improper for me to have answered an inquiry on such a subject; but as I could not authoritatively remove suspicions founded upon appearances, which taken alone, would in a great majority of cases indicate what was feared, and not the singular state of disease revealed after the death of Lady Flora, I felt it my duty, considering the very peculiar responsibility which attached to me, to confide the doubt which was in my own mind to those who had a right to demand my real opinion, and who, I felt assured, could not use it in a manner unfriendly to Lady Flora.

I shall now notice such parts of the

publication of the Marquis of Hastings as more particularly relate to me. An extract is given by his lordship from a letter written by Lady Flora Hastings to the Dowager Marchioness of Hastings, dated March 13, nearly a month after the event, in which it is stated, that at my visit to communicate to Lady Flora the suspicions entertained respecting her, I became "violent and coarse, and even attempted to brow-beat" her ladyship!—I hope I may refer to my character alone as a sufficient reply to this accusation; moreover, on the occasion referred to, there could be no motive for such conduct. Any earnestness that I may have shewn in my manner could have for its object only that Lady Flora, for her own sake, should see Sir C. Clarke on that day. In corroboration of my own solemn disavowal of the conduct imputed to me, I refer to the two notes, already given in my narrative, which I received from Lady Flora Hastings within twenty-four hours after the very occasion on which I am said to have thus acted; and, consequently, at the very time when all her feelings may fairly be supposed to have been more excited by the alleged conduct than at any subsequent period: and as still more direct evidence, I would further refer to Lady Flora's letter to her uncle, Mr. Hamilton Fitzgerald, dated March 8th, in which—although written for the express purpose of making her griefs known to a relative, with whom she had no motive for reserve, and, therefore, in the very circumstances, calculated to elicit complaint—not a word escapes her, blaming my conduct or language during either of my interviews with her. On the contrary, expressions occur which she surely could not have used had she really then felt that I had acted towards her in an unfriendly manner.

That Lady Flora intended to misrepresent what had actually occurred I do not for a moment believe. Under the circumstances of excitement in which she was placed, it need not create surprise that she should unconsciously have allowed impressions, arising out of discussions which afterwards took place, to grow upon her mind, till she at length confounded them with facts, or that she should have greatly exaggerated what did actually take place. It is only in this way that I can account for some of the statements made by Lady Flora Hastings.

Her ladyship's written account of the circumstances which took place during the interview on the 16th February, at which we alone were present, differs widely from my recollection of them. I think it necessary to notice two points in particular:—The first is the alleged diminution of Lady Flora's size. On this I shall only

observe, that I could discover no such diminution, else I should have been too happy to have availed myself of the circumstance to clear Lady Flora's character, and to have relieved myself from a very embarrassing position. The second is, that I told Lady Flora that she must submit to a "medical examination." I not only never used such an expression, but never heard it employed for what it has been assumed to imply, till after the unfortunate affair was over; in fact, I then believed that a full external examination would prove sufficient to decide the matter. Everything, consequently, which has been asserted about a "medical examination" having been suggested by the ladies, or by me, is utterly groundless.

The only other parts of Lord Hastings's correspondence which require notice from me are two charges brought forward by his lordship. The first consists of a statement said to have been received from Lady Flora's own lips, that the examination "was conducted with more than ordinary disregard to delicacy and to her feelings." In corroboration of this charge, his lordship has referred to a deposition on oath, by Lady Flora's maid, "that the conduct of Sir James Clark and Lady Portman was unnecessarily abrupt, indelicate, and unfeeling!" I notice this charge, in passing, merely to give it a peremptory denial. The other charge is in the following words: "Some questions having been put to my sister, and answered, it was suggested that the inquiry ought not to proceed further, and that they might now feel quite satisfied. Sir James Clark objected, and stated that the ladies of the court would not be satisfied without the strictest examination; and that if Lady Flora knew her own innocence, she could have no reason to oppose the most complete scrutiny." The simple reply to this is, that *no such suggestion was ever made, and no such objection ever urged*. Upon what authority Lord Hastings makes this statement he has no nowhere mentioned, and I am utterly at a loss to conceive, unless, indeed, it be on that of the foreign maid, to whose oath he before refers, and whose knowledge of English may not have been sufficient to enable her fully to understand what was passing. But I cannot avoid expressing my regret that his lordship did not procure the testimony of the only witness present during the *whole* consultation—Sir Charles Clarke—before he made such grave charges. Had he followed this course, I venture to affirm they never would have been made. Sir Charles Clarke, although he might not have thought it proper to discuss with Lord Hastings the details of what passed at the consultation, could not have hesitated,

had he been appealed to, to refute such groundless accusations.

It remains for me now only to repeat my sincere regret that I was unable to relieve Lady Flora Hastings at once from every suspicion. No one has felt more acutely than myself, during the whole of this painful affair, the distress occasioned to Lady Flora and her family, whether arising from original circumstances or from the matter being afterwards forced into public notice.

Deeply painful as it has been to me to see my name so long associated with alleged acts and motives at which my very nature revolts, the consciousness of my own rectitude, the friendship of those who, from long and intimate acquaintance, know me to be incapable of the conduct imputed to me, and a firm reliance on justice being ultimately done to all parties, have supported me under an accumulation of attacks such as few professional men can have been subjected to.

JAMES CLARK, M.D.

George Street,  
Oct. 7.

## PRIZE EXAMINATION, APOTHECARIES' HALL.

### BOTANY.

*Examination Paper, October 9th, 1839,  
Hours from 10 A.M. till 10 P.M.*

1. What is botany? What are its subjects and objects, and what the most important subdivisions of the science?

2. State briefly the opinions of Schleiden on phylogenesis.

3. Describe and give examples of fibro-cellular tissue.

4. What are bothrenchyma, pleurenchyma, trachenchyma, and eincenchyma? Give examples of each.

5. What are the compound organs in flowering plants?

6. Give the external and internal anatomy of a leaf; and account physiologically for the varied configurations of simple and compound leaves.

7. What is the chemical composition of vegetable tissue?

8. Are the membrane of cellular tissue and the subsequent deposits formed of the same chemical substance?

9. What are the conditions necessary for the germination of a seed; and the chemical and physical phenomena accompanying that process?

10. What are the effects produced by vegetation on the atmosphere?

11. What is the action of light upon plants?

12. Describe the structure of the ovulum before and after fecundation.

13. Describe the structure and give examples of the following fruits: viz.—Folliculus, legumen, lomentum, pyxidium, regma, cterio, syncarpium, nuculanum, hesperidium, pomum, pepo, and bacea.

14. Describe the circulation of the sap, both general and special.

15. What were the earliest adumbrations of the natural scheme; and what its chief progressive stages of improvement?

16. Do any of the orders abounding in dietetic plants contain poisonous species? If so, give some examples.

17. Give the characters of the following natural orders, and mention the most important medicinal products furnished by each order.—Ranunculaceæ, Umbelliferae, Violaceæ, Guttiferae, Euphorbiaceæ, Cinchonaceæ, Leguminosæ, Anacardiaceæ, Polygonaceæ, Asteraceæ, Labiatae, Zingiberaceæ, Fungi, Lichenes, and Algæ.

18. Describe, in Latin, the plants numbered 1 to 12; and name the natural orders to which they respectively belong.

1. Polygonum Persicaria.

2. Solanum nigrum.

3. Lencojum autumnale.

4. Liatris spherioidea.

5. Daphne pontica.

6. Cytisus capitatus.

7. Hydrangea arborescens.

8. Euonymus europæus.

9. Hibiscus syriacus.

10. Aloe margaritifera.

11. Jasminum fruticans.

12. Lobelia erinoides.

These plants were given to the candidates unnamed.

N. B. WARD.

Number of candidates—Eight.

## DR. BURNE'S PAPER ON THE CÆCUM.

*To the Editor of the Medical Gazette.*

SIR,

In my second memoir on the cæcum, and appendix just now published in vol. xxii. of the *Medico-Chirurgical Transactions*, I regret very much to find that the allusion to an article on the same subject by Dr. Copland in his "*Dictionary of Practical Medicine*" has been omitted, the circumstances of which I wish to explain, because of the high character of Dr. Copland's work, as well as out of regard to myself.

On account of the length of my second memoir, the Council of the Medical and Chirurgical Society returned it to me twice, urgently requesting that I would curtail it as much as possible; and, in order to meet their wishes, I, on both occasions, cut out several pages, amounting in all to 8 out of 31 MSS. in which was,

I am concerned to find, the reference to Dr. Copland and others. I should therefore feel greatly obliged to you to insert in the GAZETTE the accompanying paragraph, extracted from the copy of the memoir read at the society, as the best reparation now in my power to make.

I am, sir,  
Your obedient servant,  
JOHN BURNE.

24, Lower Brook Street,  
October 9th, 1839.

[We regret that we cannot make room for the extract, but we conceive that Dr. Burne's object will be fully accomplished by the insertion of his letter.—ED. GAZ.]

## SINGULAR CASE

OF A

## WOMAN DELIVERED OF FIVE CHILDREN.

GIUSEPPA CALIFANI, of Naples, at the age of fourteen years and three months, was married to a man aged twenty-seven, by whom she had ten children at eight accouchements; at the fifth and sixth producing twins. She lived with her husband ten years, and remained a widow three years after his death; she then took a second husband, whose age was about twenty-nine. After two regular accouchements, upon her third pregnancy she became enormously large; so that, at seven months, she appeared to be at the termination of her natural period. She was taken, however, at seven months, with labour-pains, and brought forth successfully, and by natural presentations, five living children, all of whom were baptised. The mother did not suffer any thing extraordinary. Four of these children were females, and one male. The male infant was delivered first, and after a few minutes, one female; then, after a cessation of fifteen minutes' interval between each, the other three followed. The infants much resembled each other, and were of a regular form, and well grown, and very nearly of the ordinary size of a seven months' fœtus; each weighed about  $3\frac{1}{2}$  lbs., and measured in length a French foot. The insertion of the umbilical cord was about four lines lower down than ordinary. The placentas with their membranes were four instead of five; and each had its proper umbilical cord, except the fourth, which contained two in one large sac. The fœtus, with their membranes, placenta, and umbilical cords, are preserved in the Royal Anatomical Museum of the University of Naples. Vincenzo Licci, of Calimera, in Otranto; Vincenzo Massari, of Molfetta, in Bari;

and Dr. Antonio Scacani, of Naples, conducted the examination.—*Bullettino delle Scienze Mediche*, and *British and Foreign Medical Review*.

## APOTHECARIES' HALL.

## LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, Oct. 10, 1839.

John Marshall, Chesterfield.—John Lambert, Bradford, Yorkshire.—Thomas Godfrey, King's Cliffe.—Walter John Bryant, 50, Edgeware Road, London.—William Potts, Carlisle.—Henry Sharp, Copp. Garstang, Lancashire.—William Henry May, Leicester.—Henry Rust, Dunmow.—Geo. John Vine, Hadlow, Kent.—John Waldo Fring, London.—Charles Moore Collins, Dulverton.—David Thomas Llandilo.—Thomas Watkin Williams, Ystradavellty.

## THE CROONIAN LECTURES

FOR 1839.

By JOHN CLENDINNING, A.M. & M.D.

Of Oxford, &c. and Senior Physician to the St. Marylebone Infirmary.

As delivered at the Royal College of Physicians,  
May 15, 17, 22.

### ON THE DIAGNOSIS OF DISEASE OF THE HEART.

*Varieties of the pulse.*—*Rhythm.*—*Pulse depends on dynamic condition principally.*—*Pulse ambiguous.*—*Palpitations.*—*Cases.*—*Sex and age.*—*Summary of cardiac diagnosis.*

*Pulse.*—Nothing could be more natural than the *a priori* expectation that if any vital action were, more than others, capable, by the mode of its accomplishment, of indicating the condition of the heart, that action must be the arterial pulse; and on this reasonable presumption has, it appears to me, been founded much speculation regarding the diagnostic import of various modifications of that action. But the importance of the character of the pulse has been maintained likewise on experimental grounds. Quite recently, a distinguished cardiologist of this metropolis presented to the Royal Medical and Chirurgical Society a paper in which a considerable number of varieties of pulse were pointed out as indicating various morbid conditions, and amongst the number several that he had found to indicate certain diseases of the heart. Now without contesting any of the views of that distinguished pathologist, which I should mention were given as conclusions from numerous and original facts, which facts themselves were not communicated, I will acknowledge that for my own part I have not observed more than a very few important varieties of pulse which I could with

confidence refer to known cardiac morbid conditions, and which might therefore be considered as diagnostic symptoms, and of those conditions part only are structural. The varieties of pulse I allude to are—

1. The quick pulse.
2. The slow pulse.
3. The large pulse.
4. The small pulse.
5. The soft pulse.
6. The hard pulse.
7. The jerking and thrilling pulses.
8. The intermitting and reduplicating pulses.

Respecting the quick and slow pulse little need be said. They indicate dynamic conditions only, and their causation is so multifarious that it may be held that, except incidentally and indirectly, they can have no peculiar interest in their relations to cardiac diagnosis.

Not so the large and small pulses, which both indicate important states of the heart. The large pulse implies an ample ventricle with valves and arteries in an effective condition; but it implies also a sthenic state of the cardiac parietes, in which alone it differs constantly from its opposite, or the small pulse. The latter, or small pulse, implies an arterial current of small volume and inferior power, and may arise from any of various conditions. It often occurs in ventricular disease, including both increase of weight and volume; but only, I think, after the supervention of the asthenic stage. An enlarged but feeble or sluggish ventricle expels a considerable mass of blood, but with little force, so that when the impulse has traversed the resisting arteries as far as the wrist, it is diminished below the normal standard, and the radial is feebly distended, and smallness of pulse results.

2. Another probable source of small pulse in morbis cordis, is an incomplete

systole; the operation of such a cause must be obvious.

3. A third cause is valvular defect, viz. the interior valves allowing of reflux into the veins, or the aortic orifice being more or less obstructed, by contraction or extreme induration of the valves or circumference of the aperture, &c.

4. Another cause of small pulse is probably some condition, permanent or temporary, of the great arteries, unfavourable to transmission of the ventricular impulse and current.

5. Another obvious cause is defect of proportion or quantity in the blood.

The smallness of the pulse in certain stages of typhus, enteritis, arachnitis, cancer, advanced phthisis, &c. &c., evinces the adequacy of these causes thus partly stated from observation and in part conjecturally assigned; and close observation of morbus cordis shews, or renders probable, their reality.

3. The soft or compressible pulse implies a cardiac action usually little differing from the normal.

But 4. The hard pulse indicates dynamic disease at least, whether permanent or transitory.

5 and 6. The jerking and thrilling pulses. The vital conditions indicated by these in the heart are commonly asthenic, and connected with irritation. The mechanism of their production is obscure. It is probably an abnormal tremulous systole, a contraction insufficiently equable and uniform, owing to want of harmonious action in the multitude of contractile fibres that form the ventricular parietes, the *carneæ columnæ*, and the *septum cordis*. Such are the varieties I have noted in the mechanical properties of the pulse as referable to distinct and important structural or dynamic states in the heart.

*Rhythm.*—With respect to the rhythm, I have observed nothing very specific requiring much comment on that head. This only deserves notice, viz. that irregularity of whatever kind in the rhythm of the heart or arteries is always suspicious, and that though it does not indicate directly or certainly any specific cardiac disease, yet, that when observed in connexion with certain other symptoms, it is a rational sign strongly confirmatory of hypertrophy of the left ventricle at least. Of the healthy circulation it must be remembered, a constant uniform interval between successive actions is, under like conditions as to the operations of stimuli, one of the least variable and most characteristic phenomena. A frequent and, much more, a prolonged deviation from rule in this respect must, I imagine, proceed, if we exclude the neuroses from an enduring morbid tendency,

and such enduring disposition to diseased action must have its root in structural mischief. So that even moderate irregularities in the arterial rhythm, provided that they are not constitutionally and purely nervous, as in young women, and nervous youths, portend, I conceive, grave mischief in most instances.

*Pulse depends on dynamic condition principally.*—Now of all these varieties of pulse there is but one I think that certainly indicates peculiar structural conditions; viz. the large pulse, which of necessity, I presume, proceeds from a large ventricle with effective valves. All the others indicate dynamic conditions only with sufficient constancy to render them available as diagnostic signs. The small pulse, *et. gr.* may be owing to an obstructed aortic opening, or a defective mitral valve; and the thrilling pulse may likewise arise from either of two varieties of valvular disease, but neither is always, or even generally, referable to organic mischief in the openings of the heart. On the whole, I think it may be held that the character of the pulse depends principally, 1st, on the heart's dynamic condition;—2dly, on the fluids, both as to their mass, density, and stimulating qualities; and in the 3d place only as to frequency and importance on the valvular structure. The dependence of the pulse on vital or dynamic conditions principally, is well shewn by the neuroses of females. And with respect to these diseases, I think I might almost say that I am uncertain which would be the easier task; viz. to enumerate the varieties of arterial action I have met with, or to point out those I have not met with, more especially in that proteiform disease, *hy teria*.

*Pulse ambiguous.*—I think then that, in opposition to *a priori* expectations by no means unreasonable, the pulse may be held to furnish little assistance, except as a rational sign, in the diagnosis of diseases of the heart; while, as a rational sign, it is too subject to fallacy to entitle it to much confidence in cases otherwise doubtful.

*Palpitations.*—But there is a symptom closely connected with my present subject which is of much importance; I mean palpitation, especially if attended by dyspnœa, and urgent præcordial, epigastric, or substernal distress. This symptom of chronic pectoral disease involving structural mischief in the heart, was one of the first noticed signs in cardiac disorder. From Albertini downwards, whose work is even entitled "*De Palpitationibus*," it has been by every writer I have consulted treated of as a principal sign of heart disease. To this morbid action primarily I am much disposed to refer the spasmodic asthma of the older writers, which I have for some

years regarded with the suspicion that it was a relic of exploded systems, rather than a traditional truth confirmed by recent experience. It may seem strange, but I believe it strictly true, that since I fixed my attention, now several years ago, more especially on pectoral diseases, I have scarcely met with a case of supposed asthma, in which pulmonary organic disease, and cardiac disease likewise, have not appeared to me clearly developed, in the shape more especially of bronchitis, or emphysema of the lungs, and of simple hypertrophy of the heart. But whether I am right or not in rejecting spasmodic asthma as a purely bronchial spasmodic disease, from the Nösology, it must be admitted that there is no rational sign of superior value to *palpitation*, in all cases where there is no ground for suspecting the existence of hysteria. Exclusive of pure neurosis affecting the heart, which is comparatively a great rarity so far as I have seen, amongst males above twenty years of age, and amongst females too, I think, of mature and declining years, I am aware of no disease that produces palpitations such as those so justly held to characterize disease of the heart. I have never, in any post-mortem examination of a male, amongst whose symptoms palpitation excited by exercise, passion, &c. or spontaneously arising, especially after night-fall, had clearly existed for any length of time before death, been able to find a heart *normal* in its dimensions, or *structurally sound*. Nor in any class of subjects have I ever met with the palpitations usually described as signs of cardiac disease, without other evidence of *morbus cordis*, excepting only in the cases of a few unusually nervous females, mostly under forty years of age, and subjects at the same time of hysteria in other forms. Of these cases, so wearisome to the official practitioner, so lucrative in private business, several have certainly presented symptoms of no ordinary difficulty. In the case of two, I was for a time induced by deceptive appearances to prescribe for them on principles considerably differing from those on which I usually treat neurosis in the female.

*Cases.*—Of the three most striking that I have lately met with, one was a female beyond the sexual age, labouring under dyspnoea with palpitation of long standing. The impulse of the heart was extensively felt, and the sounds were extensively audible. This case was considered by a friend of much experience a case of heart disease. However, on inquiry I learned, that the palpitations had commenced eleven years before, in consequence of a fright, and had continued with little or no intermission up to the time of her admission. I ascertained further, that she had unqui-

vocal phthisical signs, such as consolidation of both lungs to a great extent, in the upper lobes, with cough, &c.; and that the heart's impulse, though rather extensively felt, was not that of a heavy body. My diagnosis, therefore, of *phthisis with neurosis of the heart*, was confirmed some months subsequently by a post-mortem examination. Another case was that of a female under thirty, tall, large, and muscular, who was admitted into the infirmary from the lying-in wards of the workhouse, with dyspnoea, palpitation, vomiting, great pain about the præcordia, and in the epigastrie, left hypochondriac, and umbilical regions, with much tenderness, and some fever. This woman had been for some years much troubled with rheumatism, and had sciatica at her admission. There was also very manifestly a moderate hypertrophy of her heart. Her illness was protracted; but so long as I prescribed, as for rheumatism and disease of the heart, she made no decided progress towards recovery; but soon began to mend under the use of steel and the shower-bath. Her vomitings, abdominal tendernesses, palpitations, anorexia, wasting, &c. after a few weeks of anti-hysterical treatment gave place to the opposite conditions. Her menses were re-established, and she was discharged quite well. The third was an interesting case in several respects. It was that of an intelligent young person, whose alvine and uterine functions were perfectly normal, and who complained of a pain at the crown of the head, on which a hard tense swelling, like a node or rheumatic periostitis, was perceptible; and of palpitation with much pain of the whole præcordia, both on pressure and otherwise. The heart seemed to throb with unusual force, and to be palpable and audible over an unusual area. The rhythm and sounds of the heart were quite normal, but the pulse usually exceeded the standard of health. This person had been treated out of doors for heart disease, and was herself persuaded that that organ was gravely affected. Her complaints were of some years standing. Slight exertion caused distressing dyspnoea, and many features of the case favoured the notion of *morbus cordis*. On these grounds it was determined to continue for a time the cardiac treatment previously instituted, cautiously using leeches, setons, and blisters about the præcordia; and internally ordering prussic acid, digitalis, iodine, &c.: mercury was also employed. But nothing availed her permanently, until it was resolved to adopt a tonic plan of treatment, after which she improved slowly, but steadily. Under the shower-bath, and iron, with full diet, her strength increased, her pectoral distress, pain of head, &c. diminished, and she was at length discharged,

greatly relieved. During the latter part of the treatment at the infirmary, and while an out-patient, she attended the *séances* of the Baron Dupotet, where for the first six weeks no effect was visible. Afterwards, however, she was affected with what she called "confusion and giddiness" without sleep. She never attained to any of the transcendental gifts of magnetic science. For a considerable period the effects of the tonic plan commenced in the infirmary continued, after her transfer to the out-patient list, to serve her very much, and she was able to walk perhaps a mile or more at once, and several miles in a day, but she never entirely got rid of the palpitations, præcordial pain, &c.; all of which, however, seem now principally referable to cardiac neurosis.

The occurrence then of palpitations, as an habitual inconvenience, in the male after 20, and in either sex in mature years, is a rational sign of much interest and importance; and is generally found to indicate enlargement of the heart. But in such cases we are not dependent on rational signs only, for, exclusive of percussion, during the palpitation, it is easy to ascertain by the hand in most cases whether the heart is more bulky and heavy than normal, or otherwise: so that the excessive and irregular efforts of the organ make doubly manifest the cardiac disease, viz:—at once *circuitously*, i. e. by functional lesion, and *directly*, i. e. by physical evidence.

*Sex and age.*—There remain still some other topics that would require notice, if there were space, but which I must here omit. They are, sex, age, and dropsical effusion. The purport of my remarks respecting the two former would be to insist on the propriety of taking them into account in all dubious cases, as circumstances exercising unquestionable influence over the development and distribution of morbus cordis. With regard to dropsy, I have virtually to a great extent anticipated what I should have to say on that head, in the observations on renal complications. Dropsy is either local or general. The local may depend on causes of circumscribed influence, and local operation. Such are, hydrothorax from pleurisy, hydropericardium from pericarditis, ascites from peritonitis, hydrocephalus from arachnitis, anasarca from pregnancy, &c. &c. of all of which every hospital furnishes examples. But general dropsy, or dropsy manifesting itself at once more or less in the extremities, chest, and abdomen, depends, according to different pathologists, either on the heart, lungs, liver, or kidneys, or else on the condition of the blood. The hepatic and pulmonary theories of general dropsy are not at present generally received, I think, and appear to me, ætiologically

considered, quite hypothetical. General dropsy is every day to be met with without adequate lesion of structure in either organ. The heart is the organ most generally suspected, but of late the renal theory has obtained considerable and very able advocacy. On this last subject I have already offered some observations under the head of renal complications, to which it is unnecessary here to add any thing further. Suffice it to say, that those who incline to the renal theory, or perhaps I should say to the renal-sanguineous theory, admit that the renal dropsy they describe is usually, and I imagine nearly invariably, accompanied by morbus cordis.

In the same way, any pathologist that thinks the lungs or liver to be often in fault as causes of general dropsy, may be considered virtually to advocate the inclusion of pulmonary or hepatic symptoms amongst the rational signs of disease of the heart, since it is clear from my lectures for 1838, that morbus cordis is nearly invariably complicated with, and, I conceive, productive of chronic bronchitis, &c. in the lungs, and enlargement, tenderness, &c. in the liver.

#### *Summary of Cardiac Diagnosis.*

The diagnosis of the heart's condition is based upon five principal classes of facts.

1. The direct or physical evidence that is obtainable by percussion and manipulation of the cardiac region, as to the extent of dulness and impulse.

2. The direct and indirect evidence afforded by the sounds of the heart as to their pitch, timbre, rhythm, and extent of diffusion.

3. The rational or indirect evidence afforded by functional lesions of the heart.

4. The indirect evidence afforded by coincident diseases, otherwise complications.

5. The collateral evidence afforded by age, sex, constitution, hereditary predisposition, &c.

The value of the several classes of diagnostic signs above referred to varies much, appearing to graduate from something practically equivalent to certainty down to limited probability, and nearly in the order of their enumeration.

1. The first in distinctness and weight of evidence is the manipulation of the cardiac region, as practised by Senac and Corvisart, and indeed before their time. By the already described application of the hand to the præcordia, the existence or absence of any extensive hypertrophy and enlargement of the heart can be easily and certainly ascertained in nearly all cases in which the cardiac action is sufficiently vigorous. This test is subject to few important sources of fallacy, if to any. But in a very large pro-

portion of cases it is unsatisfactory, on account of debility or sluggishness in the systolic effort, and from pulmonary complications; also, sometimes, owing to corpulence, &c.

2. The next, I think, in order of certainty, when yielding distinct results, is the percussion of the *præcordia*. The sources of fallacy besetting this test are pulmonary disease, whether of increased or diminished lobular density; and too close proximity below of the liver or stomach. Owing to one or more of these circumstances, the boundaries of the cardiac dullness can, in numerous cases of *morbus cordis*, not be ascertained with sufficient precision for certainty, in defining the limits of the heart's volume.

3. The next class of signs, namely, the characters of the cardiac sounds as to their *pitch* and *timbre*, their *purity*, *order*, and *diffusion*, is often very ambiguous, and often very decisive. On the whole, the musical characters of those sounds seem of minor practical importance, since they appear very much, if not principally, to depend on fluctuating dynamic conditions in the heart. The diffusion of the cardiac sounds is likewise liable to much variation, owing more particularly to variations of density in the pulmonary lobules and lobes, so that, as a diagnostic element, it is often of little value, being difficultly rendered practically intelligible to the student, and being in several ways liable to misapprehension and misinterpretation by the practitioner in otherwise obscure cases.

With regard, however, to the other characters of the cardiac sounds, viz. their *purity*, or degree of freedom from abnormal elements, and their *rhythm* or mutual proportions, and order with respect to the systolic and diastolic efforts, those characters are of great value and importance. With respect to the former, it appears that, exclusive of pericardial friction, a permanent abnormal character of either of the heart's sounds, practically speaking, implies valvular disease, with muscular hypertrophy, and increase of the heart's volume. And the same inference is deducible from permanent suppression of either cardiac sound, or from a masked state of the sound, owing to any coincident abnormal murmur originating in the heart, or at least within the pericardium. Evidence of structural valvular disease is therefore usually decisive of a morbid condition, both structural and dynamic, of the cardiac parietes. But valvular disease being absent in most cases of *morbus cordis*, no assistance can be had, in the majority of examples, from this character of the cardiac sounds.

The relative proportions as to loudness and duration, of the systolic and diastolic

sounds, seems, where there is no valvular mischief, to depend principally on dynamic conditions of a fluctuating nature, and to be, in general, of uncertain import as a diagnostic sign. But the suppression or reduplication of a sound, in cases of pectoral disease, always nearly implies structural mischief: the former usually indicating extreme defect at the arterial orifice; the latter denoting usually imperfect and intermitting systolic effort in a diseased left ventricle, and both affording evidence, little liable to error, of hypertrophy usually with enlargement of the heart.

Of the third class of evidences, or cardiac functional lesions (one or two of which have been unavoidably noticed under the last head), the most frequent, and in many cases the most important, is palpitation. This sign is rarely wholly wanting, if ever, in *morbus cordis*; often it is spontaneous, at night more especially, when it occurs with great pulmonary embarrassment and consequent dyspnoea, and constitutes sometimes *angina pectoris*, and sometimes the most common and worst form of asthma, according to the apparent predominance of pulmonary or cardiac disturbance. But in many cases it is not present, unless excited by exercise, passion, stimulant ingesta, &c.; and of all ordinary excitants, the most effectual is quickly ascending stairs, or other inclined planes or passages. The presence of this lesion in suitable circumstances, in adult males and in females past child-bearing, indicates always with high probability hypertrophy of the heart, and is suspicious in all cases not clearly hysterical in their nature.

4. The fourth class of diagnostic signs is complications. Those seem to me of much value, more especially the pulmonary and hepatic. Bronchitis, *œdema pulmonum*, emphysema, one or more, I have seldom known wholly wanting in confirmed *morbus cordis* after the fortieth year; indeed, through their means I have often enough been able to satisfy myself about a case the diagnosis of which was rendered obscure, in certain respects, by their presence. Enlargement of the liver, with or without tenderness, general dropsy, and albuminuria, are other coincident states that greatly aid the diagnosis. So frequent, indeed, and well marked, is usually the hepatic complication, that the frequently attendant serous effusions are commonly attributed to disease of the liver. And the coagulable character of the urine, commonly referred to primary renal disease, is, however originated, generally present, so far as my observations extend, in cardiac disease. To the preceding are to be added vertigos, headaches, and other signs of encephalic

plethora, and in advanced life apoplexy, &c. as indicating a cerebral condition commonly associated with morbus cordis.

5. The last head of diagnostic evidence is the collateral evidence afforded by age, sex, conformation, and predisposition, whether hereditary, or acquired through blows on the præcordia, rheumatism, &c. Respecting those sources of information, it is sufficient to say that mature years, the male sex, and an athletic conformation, indicate a predisposition to morbus cordis, as compared with the opposite conditions in all cases; and in suspected cases are circumstances strongly, though generally, and therefore somewhat vaguely, corroborative of the existence of the disease. Ascertained predisposition, whether original or derivative, is of self evident importance. Of all morbid conformations, that of the subjects of pectoral spinal distortion involves perhaps the strongest tendency to disease of the heart.

On the whole, it may be held, I believe, that the diagnosis of disease of the heart is usually, as to its leading features, of very easy accomplishment, and that there is commonly little difficulty, either by direct or indirect means, of ascertaining whether the heart's structural condition be that of hypertrophy or not, and whether its dynamic state be asthenic and ataxic, or the reverse; but that, with respect to the different cavities, orifices, and valves of the organ, we have in many cases no sufficient means of certainly diagnosing their diseases, nor, in the present imperfect state of therapeutics, much reason to regret such defect in our diagnostic resources.

## ON SYPHILIS.

By HERBERT MAYO, F.R.S.

Senior Surgeon to Middlesex Hospital\*.

[For the London Medical Gazette.]

*Origin of syphilis—Opinions laid down by Hunter, Abernethy, Adams, Carmichael—One virus assumed to be the source of all the varieties of syphilis—Complaints not syphilitic, but in which the virus may find entrance unobserved into the system—Excoriation—Herpes præputialis—Warts.*

SYPHILIS†, lues venerea, lues, is a disease produced by contagion, and evinced

by certain local effects or primary symptoms in the part to which the contagious matter has been applied. These are followed by impaired health and special affections of the skin and throat, of the iris, of the joints and bones, and occasionally of other parts, constituting the secondary symptoms of syphilis, or confirmed lues. The ulcer, which forms the local affection, commonly occurs on the genital organs, but it may exist on any other part of the cutaneous surface, or upon the lining of the mucous passages. Secondary syphilis is not contagious, but it may be directly communicated by the mother to the fetus *in utero*.

The subject naturally divides itself into two parts:—the nature and treatment of the local affections which precede confirmed lues;—the history and treatment of the secondary symptoms of syphilis. Previously, however, to entering upon either of these subjects, there are two questions to be disposed of, the discussion of which will bring under our notice some remarkable general features of the disease, and at the same time get us conveniently through a mass of explanation as to the peculiar opinions of those whose labours have most contributed to advance our knowledge of syphilis. The questions to be prefatorily examined are,—when and how did syphilis take its origin? secondly, is there a plurality of syphilitic poisons?

The first question we are led to ask because we find there was a time, and that comparatively a recent one, in which the disease was thought to commence, and when contemporary observers and writers looked upon and described it as a new pestilence.

The period at which syphilis first attracted general attention was the close of the fifteenth century, when its ravages suddenly extended over the continent of Europe, and its symptoms displayed a virulence and rapidity unknown at the present time. Astruc, in his treatise upon the venereal disease and its origin, has collected the testimony of numerous writers who flourished at or soon after the period mentioned. It will sufficiently answer my purpose to quote a few of his many authorities. Joseph Grunbeck, a German physician, who wrote in the year 1496, uses these expressions respecting syphilis:—"Labem esse tam repente in homines demissam, ut plaga cunctis decussa esse videatur.

\* This and the succeeding communications on the same subject are the substance of that part of Mr. Mayo's surgical lectures which treats of syphilis, prepared by himself for publication. The quantity published each week has reference to the space we can allot to one contributor.

† Syphilis, from σφίλος, odiosam et invisam faciem habens.

.....*Novum esse genus morbi naturæ invisum*” Alexander Benedictus, of Verona, who had served as a physician in the army of Charles VIII. and seen the eruption of the disease in 1496, uses the words, “*Venerco tactu novum, sed saltem medicis ignotum prioribus, morbum gallicum ad nos ex occidente irrep- sisse.*” Finally, Gaspard Torrella, a Valentinian, once a physician, but then a bishop, thus describes, in 1500, the occasion when the disease broke out:— “*Gallis manu forti Italiam ingredientibus, et maxime Regno Parthenopæo occupato, et ibi commorantibus, hic morbus detectus fuit. Ideirco ab Italīs morbus gallicus cognominatus fuit, arbitrantibus ipsūm Gallis commaturum esse. In Galliā vero, quia in reversione Regis Caroli cum suis in Galliam, hic morbus apparere incepit, credentes Galli se cum ex Napoli apportasse, hanc ob causam morbum Neapolitanum vocarunt.*”

Upon this and similar evidence we are entitled to conclude, either that syphilis originated in or was first introduced into Europe at the close of the fifteenth century, or that, having previously existed there in a milder form, its symptoms became of a sudden frightfully aggravated. The following ingenious reasons are advanced by Mr. William Becket, in the *Philosophical Transactions* for 1731 and 1732, which favour the latter hypothesis. Local venereal disease, communicable by contagion, had been known in Europe long before the year 1500; and legal enactments had been made, of which curious instances are given both by Astruc and by Becket, to check its spread. Under the vague name of leprosy, again, a state of disease prevailed which, in many of its features, corresponded with lues; and directions even had been given as to the means proper to prevent its communication through intercourse of the sexes. It is therefore possible that among the affections grouped under the name of leprosy, secondary syphilis existed, its connexion with primary venereal disease being as yet generally unsuspected? Leprosy, it may be remarked, went out when syphilis came in, and Locks now appropriated to syphilis were originally provided for the reception of lepers.

It would be drawing this thread of conjecture too fine to speculate on the cause of an effect itself hypothetical, and to at-

tempt to trace the supposed aggravation of the disease to events of the period when syphilis first forced itself on the attention of the world. Yet in our own times there has been experience of more than one sudden increase of the severity of the venereal disease; and it is remarkable that the occasions to which I refer have been the march of armies into foreign countries. After the battle of Jena, Baron Larrey, in giving an account of the French quartered in Berlin, observes, that *the most serious malady was syphilis*, with which considerable numbers of the troops were infected, and which in many presented a very troublesome character. In our own troops in the Peninsula the same circumstance was observed. “In the British army,” observes Dr. Fergusson, “in 1812, more men have been mutilated by primary venereal sores, during the four years that it has been in Portugal, than the registers of all the hospitals in England could produce for the last century; while venereal ulceration has not only been more unyielding to the operation of mercury than under similar circumstances at home, but the constitution, while strongly under the influence of the remedy, has become affected with the secondary symptoms in a proportion that could not be expected.” Dr. Fergusson attributed the destructive effects of the venereal virus when transmitted from the natives of Portugal to the British, partly to its being in some measure new—a branch of the virus which had become modified by passing for several centuries through a stock of different habits, constitutions, climate; partly to the state of health of the parties who received the infection. It is to be observed that the Portuguese, who communicated the disease in this virulent form to our men, experience it themselves in the mildest form, for which they never take mercury.

Now if we are at liberty upon the strength of these instances to suppose that the effects of the poison of syphilis are sometimes aggravated when the disease is transmitted by the natives of one country to those of another, (a circumstance which can only be well ascertained when numbers are simultaneously collected under medical observation,) we seem to understand why, in the French invasion of Naples, the disease, on the supposition that it before existed in a milder form, might suddenly have

became virulent there. It is true, a difficulty would still remain in accounting for its general diffusion in the aggravated form through Europe.

The preceding argument tends likewise to exonerate the followers of Columbus from the imputation of having imported syphilis from the West Indies. But if we may believe Mr. Bacot, from whom I quote the following statement, there is better testimony in their disculpation:—As early as 1488, Peter Martyr, who was physician to the King of Spain, writing to Arius Lusitanus, the Greek professor of Salamanca, adverts to the new disease of their times, and specifies the “*membrorum hebetudinem, juncturarum omnium dolores, ulcenum et oris feditatem*,” which accompany it. Now the same physician was at Barcelona when Columbus made his appearance there after his first voyage, but he does not say one word about the importation of the disease in any of his writings. Neither does Columbus, nor his son Ferdinand, who wrote the history of his father's life, in which he gives a description of all the diseases which afflicted the Spanish adventurers up to 1493.

The question next to be considered is, whether there are one or more syphilitic poisons; that is to say, whether the diversities which manifest themselves in the features of the disease are attributable to differences existing in the material of infection, or in the condition of body of the recipient.

It is desirable to look as far back as the publication of Mr. Hunter's views to elucidate this inquiry. Mr. Hunter held that there was one venereal disease, presenting certain definite primary symptoms, and which was in all its stages distinguishable from affections resembling it by yielding to the influence of mercury, which he considered its proper, exclusive, and specific remedy. However erroneous the view so stated will be proved to be, or to whatever extent rather it may require to be modified, it would be unjust to that great surgeon and physiologist not to admit that in his writings much is accurately and philosophically observed of the nature of syphilis, and that especially the following important observations are due to him.

I. The recognition of a special form of local ulcer as characteristic of the syphilitic poison. And it is remarkable

that although we now admit that local ulcers of another character are liable to follow impure intercourse, and to infect the system, still the opinion universally maintains its ground, that the appearances specified by Hunter are most decisive as to the nature of the disease.

II. The recommendation, only too strongly expressed, of the employment of mercury in the complaint so identified. Agreeably with which it is in that particular form of the complaint that surgeons are still agreed upon the propriety of employing mercury.

III. The theoretical principle, that mercury cures venereal action, but does not remove the *disposition* previously formed, and which is not yet come into action. A proposition true at the present time, if we alter it to this form—that in the cases to which mercury is applicable it removes the existing symptoms, but does not prevent, when the constitution is already affected, new classes of secondary symptoms manifesting themselves.

IV. The expression of the principle, that although mercury does not destroy the disposition already formed, yet that it prevents it forming. In other words, that mercury administered for certain primary symptoms tends to prevent constitutional lues.

V. The recognition of the fact, that the matter of secondary syphilis is not infectious. A principle the correctness of which has finally been demonstrated by the experiments of Ricord.

It is interesting to observe, what, and how little modification, upon these important points, Mr. Hunter's opinions admit of, from the enlarged science and observation of the present day, and how near and like they are to truth. Mr. Hunter was himself fully aware of the extent of the field which he left unexplored, and of the existence of a number of cases resembling venereal cases, which are rebellious to his principles; and these he adverts to, and in a degree exemplifies, and recommends their investigation to his successors.

Mr. Abernethy, in his views the closest follower of Hunter, pursued with diligence the examination of the irregular cases of syphilis, or of those which would not yield to mercury. These cases, supposing them of spontaneous origin, he classed together under the head of pseudo-syphilis. But he in no respect disencumbered himself of the

erroneous opinions of his eminent predecessor. One of Mr. Hunter's incorrect generalizations was, that the disease once established "goes on increasing, without wearing itself out." And we find Mr. Abernethy thus expressing his conviction of the truth of a branch of this false doctrine, while at the same time he was adding useful materials to the general stock of information respecting the disease.

"A very simple fact," observes Mr. Abernethy, "has enabled me, in most cases, to distinguish between the two diseases (syphilis and pseudo syphilis), yet, simple as it is, if it be generally true, it is very important; and if it were universally true it would be of the highest consequence. The fact alluded to is, that the constitutional symptoms of the venereal disease are generally progressive, and never disappear unless medicine be employed. It may be added, too, they are as generally relieved under an adequate effect of mercury on the constitution." We now, however, know, in contradiction of the principle so laid down, that in a great majority of cases, the venereal disease, left to itself, or without any assistance from specific remedies, has a tendency to wear itself out; that not only single attacks of secondary symptoms, to which Mr. Abernethy more particularly refers, will subside without the use of medicines, but that the natural course of the whole disease, is, in most cases, towards a spontaneous cure. This important pathological principle, to which I shall afterwards have occasion more fully to advert, has been established by the scientific inquiries of the army surgeons of this country, among whom the principal credit is due to the late Mr. Rose.

The next step in the progress of our knowledge respecting this disease was made by Dr. Adams, who, although adhering to Mr. Hunter's error, that the curableness of the disease by mercury is a test of syphilis, was led to discriminate one important variety of venereal disease, and to separate it from that with which Hunter was familiar. Dr. Adams was the first to separate phagedæna from chancre, while at the same time he advanced the opinion that the two proceed from different morbid poisons. Thus, after describing a well-marked case of the former disease, he observes, "that the case related was the effect of

a morbid poison introduced from the broken skin at the lower part of the prepuce, can hardly be doubted; and that it was not venereal is to me equally certain. Is it consistent (he says) with what we know of the latter, that an ulcer should increase while mercury is showing its effects on the constitution?" In a practical point of view it is comparatively of little consequence whether phagedæna proceed from a different virus to that which produces syphilis: if the decision of this question is finally given against Dr. Adams, it will in no degree diminish the value of his judicious separation of the two diseases.

Dr. Adams thus recognized in primary sores two kinds, dependent upon two different poisons; the one curable, the other incurable, if not aggravated, by mercury.

We are indebted to Dr. Carmichael for the next step in originality and usefulness towards a fuller knowledge of syphilis. Dr. Carmichael not merely has extended by his observations our acquaintance with the subject of venereal phagedæna, but he established our knowledge, by accurately describing them, of certain other local affections, some of them giving rise, in his experience, to definite and peculiar constitutional affections, from which he inferred that besides the disease recognized by Hunter, and the phagedæna brought into observation by Dr. Adams, there is a separate and third disease, resulting from a third morbid poison, having its own laws and character, and requiring appropriate treatment. I confess, however, that my own observations have not borne out the views entertained by Dr. Carmichael; while I admit that we have no work on syphilis which displays more exactness in the delineation of the disease, or has done more towards leading others to distinguish and recognize its various features, than the treatise of Dr. Carmichael, which unfolds those views. Recognizing the fidelity of the descriptions given by Dr. Carmichael of different primary sores, and of consecutive general affections, I have not found the two as regularly associated the one with the other as he represents; and I am disposed to view the conjunctions, which he considers as instances of the laws of these diseases, as accidental only.

Are we, then, to begin with the assumption that there exist, if not three,

at least two venereal poisons? I think it safer to adhere to the opposite, which I believe is the general opinion, and to attribute those numerous diversities which are met with to temporary or permanent peculiarities in the habits of the individuals affected. My full reasons for preferring this opinion, the holding which is not of course inconsistent with allowing the existence of every variety of character and feature, and with attaching the utmost importance to the study of those differences, will be found in the course of the account of the disease, which I propose to give: it may be as well, however, now to introduce one or two cases in support of this view, which show that to some extent at least it certainly holds good. The first case is one by Dr. Fergusson, in a paper in the *Medico-Chirurgical Transactions*, which I have already quoted.

An officer, four days after having connection with an opera-dancer at Lisbon, applied to Dr. Fergusson, with the whole penis enormously swelled, of a deep red colour: there were chancres on different parts of the prepuce, and two on the glans penis, "the appearance of which could be compared to nothing but the holes made in a piece of mahogany or log-wood." He was a young man, robust and plethoric. The skin was hot, the pulse sharp and quick, tongue white, eyes suffused. Being copiously blooded, and cold acetic lotions having been applied to the part, and free purging obtained with neutral salts, the tumefaction subsided, and the sores became healthy. The person who communicated the infection continued on the stage for many months afterwards, apparently in perfect health, but occasionally infecting others, yet without any thing extraordinary that was learned in the nature of the symptoms.

The other instance is from Mr. Rose, who observes, "I recollect many years ago a healthy young man, who was affected with a decidedly sloughing sore in the penis, in consequence of a suspicious connexion. He twice afterwards, at a very considerable interval, had a fresh infection, and the sores each time had the same character as the first."

I now proceed to describe the primary symptoms of syphilis and their treatment, assuming that they result from the application of virulent matter

secreted from a sore upon an infected person, to a vascular surface, by which the virus is imbibed or absorbed.

It is, indeed, a question, whether syphilis may not be introduced by contagion into the system, without any primary symptom or local sore, or sensible breach of surface. Every surgeon must have met with cases where decided symptoms of secondary syphilis existed; yet, in which the patients, where there has been no motive for concealment, have retained no recollection of any antecedent local affection. In some cases, again, the patient remembers having had a suppurating gland in the groin, but denies having had any discharge or ulcer on the genitals. Such statements it is, perhaps, impossible not to view without suspicion of their accuracy, and that without imputing to the patient any intention to deceive. A gentleman consulted me for a large burrowing ulcer on one side the glans penis; there was some swelling and redness round it, but it was not painful. I found that he had a smaller circular ulcer, a third of an inch in diameter, on the other side, of the existence of which he had not an idea. This, I have no doubt, had been in existence ten days or more, and it might have healed under treatment given for the other, without the patient knowing that he had this ulcer. So I conclude that it happens occasionally that a patient entirely overlooks the existence of the primary sore, which heals without the use of remedies. And this may be, and most probably is, the true explanation of all cases of secondary syphilis, supposed not to have been preceded by a primary sore. Nevertheless, it is not impossible that the venereal virus lodged upon a surface may make its way into the system without causing a local ulcer at the point where it has found entrance. The process by which poisons are introduced into the system is probably twofold; one effected by the circulation, the other by the lymphatics. In a wound into which the stronger vegetable poisons are inserted, or when the same are injected into the intestine of an animal, it is experimentally certain that the poison permeates the adjacent porous textures, as it would, being in liquid solution, penetrate a sponge; that, among the other textures, it penetrates the coats of the blood-vessels, upon which it reaches the blood, and

becomes mixed with it, and poisoning takes place. But in the introduction of the morbid poison of syphilis, the mechanism of absorption appears to be different. The liquid containing the virus being applied to a vascular surface, or one protected by a cuticle so thin as to offer no sufficient impediment, permeates or is imbibed by the vascular surface, and is incorporated in it. In the common course of events, the presence of the virus in the cells of the tissue irritates it, and inflammation and an ulcer ensue, that ulcer forming matter of the same virulent kind that infected the part, and the absorption of the infected portion of skin carrying the taint into the habit. But supposing this to be a just account and theory of the ordinary process of venereal absorption, it is not inconsistent with what is known of the occasional impassiveness of the system, to suppose that the imbibed virus may sometimes not irritate, but growth go on as usual, deposition and absorption balancing each other as in the healthiest condition of the part, and the virus making its way into the system silently and unobserved.

Again, it may be considered as certain that the venereal disease may be conveyed into the system through any common abrasion of the surface, or rather, that constitutional lues may occur, where nothing has gone before but a sore lasting a few days, and looking like a common excoriation. A gentleman consulted me for what appeared a common excoriation on the reflected portion of the prepuce, near the corona glandis. I advised him to apply a shred of lint dipped in a lotion of calomel and lime-water, to heal it. It closed in two or three days, and he went into the country, where he took active exercise, it being the hunting season. In six weeks he returned to town to shew me a trifling swelling in the groin; it was an inguinal gland, barely enlarged, and obscurely tender on touch. This symptom disappeared in a day or two; but I observed that the skin of his abdomen and loins was mottled, and I learned that he had rheumatic pains in his back and shoulders; then syphilitic psoriasis appeared on the head and palms of the hands, with the same affection of the throat, and his hair began to come off. The complaint was extremely mild, and he has recovered without the use of mercury; but it certainly was syphilitic,

and he had had no primary sore, except occasional excoriations like that which I saw.

These circumstances considered, it will best serve to convey a complete practical knowledge of syphilitic disease to introduce under the same head an account of all the local affections of the genitals which are known or suspected to have been connected with the introduction of pus into the habit. They may be divided into such as are very rarely, and, as it may be conjectured, accidentally, followed by lues; secondly, those for which, while they present the greatest dissimilarity to the disease as described by Hunter, mercury is certainly not a specific—namely, the two kinds of phagedæna; thirdly, those forms of disease which are nearly allied to, and include that described by Hunter, and in which, in general, mercury may be advantageously given.

I. The first class of affections comprises excoriations, herpes, and warts.

Excoriations arise from the cuticle splitting and being abraded. Their common seat is the præputium, a quarter to half an inch from the glans; but sometimes the frænum, or the adjacent surface, is excoriated. There is seldom more than one point excoriated at a time. The excoriation at first bleeds, after which for a few hours it looks like what it is—a raw surface; then it becomes covered with a thin film of grey lymph; by the third day it is generally healed, the cuticle having been replaced. Excoriations are sometimes several days in healing, the lymph becoming organized, and changing into granulations. In shape they are commonly oblong, with an irregular edge, the surface and edge being soft and sore.

To promote the healing of an excoriation, the part should be washed with soap and water, and a shred of lint, dipped in cold water, afterwards applied twice a day. There is no objection to dipping the shred of lint into the liquor. plumbi subacet. dilut., or into a wash of calomel and lime-water.

Herpes præputialis is a vesicular complaint of the foreskin, a small, circular, or oval patch of which becomes red and swelled, and itches. After a few hours it is covered with a crop of vesicles, as big as pins' heads, or something bigger; if these are on the external surface, they break and dry up in two or three days;

if they are on the inner and moist surface, they generally form as many shallow ulcers, which, if the part is kept clean, and a shred of lint applied, heal in two or three days more. Sometimes a crop of vesicular sores of the same nature forms around the corona glandis. Occasionally a red patch is seen on the glans penis, upon which two or three vesicles form, break, and dry up. Washing, and the shred of lint, as for excoriations, are all that is required. Without these means the vesicles, or little ulcers, dry and heal a day or two later. Some persons are more liable to herpes than others. Whatever irritates the urethra tends to produce it; so the removal of a stricture has been found to lessen the tendency to this complaint. Washing with salt and water, or with a weak solution of corrosive sublimate, I have known of use, where the disposition has been troublesome. It is needless to say, that all that tends to heat the system increases the disposition where it exists.

Occasionally, when the foreskin is long, the aperture is liable to thicken and chap, or become fissured. Frequent washing, the application of simple cerate to prevent the urine irritating, and of a lotion of mercury and lime water, with the avoidance of what may heat the part or the system, will quickly cure the complaint.

Warts are formed of the papillæ of the skin produced in fine villi covered with thickened epidermis; they are therefore vascular and sensible; their texture is harder or softer, and their colour grey or red, according to the quantity and density of the cuticular part. Their surface is spongy; they grow either as a continuous bed from some extent of the skin, or in clusters of separate warts, in contact or detached. Generally they are broader than high, and have a broad base; sometimes they are elongated or pedunculated. They generally follow gonorrhœa, and seem to arise from the irritation of the skin by the gonorrhœal matter.

Warts most frequently grow on the preputium near the corona glandis; sometimes on the glans; sometimes on the outer surface of the prepuce; sometimes on the perineum. In women, the external labia and the perineum are their usual place.

Warts covering a considerable extent of surface, and not elevated,

forming a broad but shallow growth, will usually disappear under the application of mercurial ointment. If this remedy is insufficient, the next to be mentioned are to be used.

Ordinary clusters of warts, thick and broad, should be washed with acetic acid, or touched with nitrate of silver; or, if refractory, they may be cut away, or destroyed at once with strong nitric acid, or the chloride of zinc paste.

Warts that are long should be cut off with scissors, and nitrate of silver applied to the wounds.

Besides the preceding definite breaches or alterations of the surface of the genital organs, there fall under the same head the consequences (in these or on any casual fret or lesion of the skin) produced by over excitement of the parts, irregular living, and neglect of cleanliness; such as extensive superficial ulcerations of the glans and lining of the prepuce—elevated fungous patches secreting pus—and other inflammatory accidents, which may at the same time mask siphilitic infection.

[To be continued.]

## FETAL MALFORMATIONS.

*To the Editor of the Medical Gazette.*

SIR,

Mrs. — was delivered, during the eighth month of pregnancy, of a living child, by the breech. The child died on the eighth day, from the effect of the following deformities:—

On the lower part of the abdomen, extending from half an inch above the navel to the coccyx, was a rounded, uneven, irregular, injected surface, consisting of thin integument, largely developed labia majora, and internally lined by peritoneum. Through this surface, about an inch below the navel, had prolapsed nearly four inches of intestine; and immediately below this prolapsus was a hole, into which a probe passed for about an inch and a half. Between this hole and the anus, which was imperforate, were two slight folds of mucous membrane, connected at the mesial line, resembling the nymphae.

On opening the abdomen, the symphysis pubis was found to be widely separated, and there was no distinction between the abdominal and pelvic cavi-

ties. The prolapsed portion of gut, already described, consisted of the entire cæcum, appendix vermiformis, and three inches of small intestine. The hole beneath this led into an imperforate rectum, nearly two inches long, which terminated just within the situation of the anus.

On each side of the rectum was situated a tense and somewhat pyriform body, about the size of a small walnut. When cut into, there escaped from these bodies a thick, coherent, albuminous fluid, retaining the shape of the cavities in which it had been confined. Each of these was evidently an enlarged vagina, having the transverse rugæ of that canal, with an os tincæ at its internal extremity leading into a small uterine cavity. The fundus of such uterus was pointed, and terminated in a fallopian tube with a single ovary. Externally the vaginæ were imperforate, and ended on either side of the union of the nymphæ before alluded to, being covered only by thin integument.

The kidneys were of unusual size; the ureters were large, and ended in the fleshy mass of which the labia majora consisted. Through these it is probable that the urine escaped during life. There was no urinary bladder.

The subject of the following abnormal structure was born alive, but very shortly afterwards died.

The abdomen was greatly enlarged, the pelvis spread open, and the whole lower extremities very much wasted. Almost the entire abdominal cavity was occupied by a very enlarged and distended cæcum, which thrust upwards the small intestines, and separated the symphysis pubis to a distance of nearly two inches. This cæcum contained several ounces of fluid.

The ileum terminated in the substance of the cæcum, but without communicating with its cavity; a few inches of the end of the ileum being very distended with meconium, none of which entered the cæcum, the fluid within which was perfectly clear and transparent. There were two openings communicating with the cavity of the cæcum, one of which led into a very enlarged and hypertrophied appendix vermiformis, the other, at its opposite extremity, into about six inches of large intestine, the cavity and coats of which were of the normal size and thickness. This gut terminated in

the anus, which was imperforate. Both the appendix and the terminal intestine were filled with the same fluid as that contained in the cæcum.

The other viscera were not examined.

I am, sir,  
Your obedient servant,  
JOSEPH STACE, Surgeon.

Southampton, Sept. 30, 1839.

## OBSERVATIONS ON THORACIC TUMORS.

By J. B., M.D.

[Continued from p. 51.]

[For the London Medical Gazette.]

IN continuation of the subject of intra-thoracic tumors, I purpose in this communication to lay before the profession the history of a few cases of this truly-interesting pathological condition of the pulmonary viscera; at the same time it must be lamented by all that our diagnosis avails but little, and is only of importance in a scientific point of view.

That the thoracic organs, and especially the lung, are much more frequently the seat of malignant disease than is generally admitted, I am fully convinced; and am inclined to believe that they are often overlooked in consequence of this too-prevailing idea of their rarity: for it would be absurd to suppose that locality can have any influence on their production, and have a greater opportunity afforded to some individuals for their inspection than to others. We again repeat, that we do not presume to draw a diagnosis between cancerous tumors and other morbid growths, or even aneurism; this would indeed be asserting for auscultation a claim which, *as yet*, it does not quite possess. That there are some cases of intra-thoracic tumor the nature of which can be detected before death, is certain, but, comparatively speaking, they are exceedingly rare; and we are very frequently obliged to content ourselves with the mere physical diagnosis of "a tumor," without presuming to pronounce an opinion as to its nature.

In that incomparable work on the "Diseases of the Chest," by Dr. W. Stokes, we have for the first time a description of cancer of the lung introduced to our notice with any thing like the prospect of being able to make a diagnosis approaching to accuracy; and in the cases narrated by this second

Laennec we at once see the extreme difficulty that there was in forming a conclusion as to the nature of the cases in question.

As Dr. Stokes properly observes, cancerous disease of the lung is met with in two forms: in the first a degeneration of the lung occurs, and the organ is transformed into a cancerous mass without the production of any tumor; in the second, the schirrous or encephaloid matter forms a tumor, at first external to, and ultimately displacing, the lung. Now, as he observes, the first is of much more uncertain diagnosis than the latter, because here we can only have the signs of solidity, whilst in the last we have displacement of parts to aid us. But since the publication of these cases, it must be admitted that our means of diagnosis has been considerably improved. There is, however, a fact connected with the first of these divisions adopted by Dr. Stokes, which, I think, merits observation, and has not, as I am aware, attracted sufficient attention, viz. the occurrence of "interrupted cancerous deposition" in the substance of the lung; two cases of which I have seen uncomplicated with any other affection, and one in which there existed miliary tubercles. The physical phenomena resulting from such a condition of the lung is very inadequate to afford any grounds for diagnosis, but, as will be seen hereafter, may sometimes become available and very important.

The assistance received from collateral circumstances in cases of cancer of the lung become of immense value when any doubt or great difficulty exists as to the nature of the case, and in the absence of positive evidence we must by these negative means assume our position. In Dr. Stokes's first case this point is fully exemplified; and but for the fact of his not having observed the disease before, he would have at once come to the conclusion of the disease being cancerous, or better, that the disease of the lung was identical with that observed on the body. Again, in cases where we are cognizant of the fact of cancer having affected the testicle, for instance, and extirpation of the parts has been performed with the hope of removing the disease; if in such a person, for example, the side sounded dull on percussion, yet without the accompanying physical signs of a great empyema on the one

hand, or of pneumonia or tubercular solidity on the other; add to these, displacement of the veins, perhaps dysphagia and sense of suffocation in some cases complained of—we may, I say, in such a case, with tolerable certainty, pronounce the disease to be cancer of the lung. Unfortunately, however, for diagnosis, such a rare combination of fortunate signs is but seldom so nearly grouped for us, and cases do occur in which the more prominent of the physical signs enumerated are altogether absent. The patient may never have dysphagia, or difficulty experienced in swallowing solids or fluids, referring the obstruction to a point corresponding to the lower part of the trachea; he may never have dyspnoea, and no affection of voice. And, on the other hand, as if to offer an additional difficulty, the cancerous deposit may be in such a condition as to afford no field for physical diagnosis, as occurs in "interrupted cancerous deposit." In this case, what is the condition of the lung? We find the organ studded over, in a pretty uniform manner, with numerous small masses of a yellowish-white substance, some as large as a shilling, others smaller and of a firm consistence, the inter-spaces being perfectly pervious, and to all appearance perfectly healthy. Now to what physical phenomena would such a condition give rise? The answer is simple—to none! whilst these masses retain their consistence, and the healthy portions remain pervious to air. The extent of consolidation is not sufficient perceptibly to diminish the sound on percussion, and the character of respiration is not discordant to the most practised ear. But even admitting that one or more of these masses were so far softened down, and permitting the entrance of the air caused a distinct gurgling; or in other words, suppose we detected a localized bronchitis, would we be justified in arriving at the conclusion that the disease was cancerous? In the absence of other signs or symptoms, certainly not; and it is in such cases more especially that the stethoscopist is foiled. All we can do is, to announce the simple fact that "there is a cavity." If, however, we are accurate in our observations of the case, collect our information both from the patient himself, and from the painful, though too often fatal murmurs (if I may use the expression) of the disease itself, we may frequently be enabled

to say what the disease is not, if we cannot pronounce its character, which, in the absence of certain and accurate diagnosis, is better than actual error.

CASE.—A young man of ordinary make, about 5 feet 8 inches in height, applied for medical aid under the following circumstances:—

He had always enjoyed very good health, until within the last year, when his health began to decline, and he lost his appetite; he was seized with an irritating cough, unaccompanied by any expectoration, and which became aggravated on the slightest attack of cold; he never has been so very ill as to compel him to keep his bed for any length of time; at present he is rather reduced, and is not capable of undergoing great exertion; complaining of pain or a sense of tightness in his chest; cough with mucous expectoration, and his respiration rather hurried; evidently has taken a cold; pulse 100, not very feeble; bowels moved once this morning. On physical examination, the chest sounded every where clear on percussion; no flattening of the clavicular regions; on applying the stethoscope under these latter regions the respiration is exceedingly puerile, much more, however, in the right lung than in the left; and at the nipple well-defined and distinct mucous rale is audible; this sign is heard over a very small space, and beyond it the lung seems every where pervious, but the respiration exceedingly loud and quick; in the left lung, and at the postero-inferior portion of that organ, a well-defined gurgling rale is audible, and higher up and nearer the spine bronchitic rales are heard almost as fine as the crepitus of pneumonia; the glands under the axilla are enlarged as well as the inguinal glands.

He was ordered to be cupped posteriorly, and a large blister applied to the chest; and Dover's powder at bed time, with Vin. Ipecac. Syrup. Simpl. et Træ. Hyoseyam.

Now what was the nature of the disease with which we had to grapple? Let us examine the symptoms or signs as they presented themselves. Here is an individual labouring under a disease of his lungs evidently, and which partakes very much of an acute attack of some kind; on percussion there is decided clearness; no flattening of the chest; no night sweats; cough, with mucous expectoration. The lungs seem

generally pervious to air, but we detect in various situations well-marked gurgling. Certainly, so far as these signs go, they afford, indeed, but very unsatisfactory and negative information; that it is just possible for the disease to be tubercular, may, perhaps, be granted to those who would incline to such an opinion, but I confess I cannot call to mind any case of incipient phthisis (which, to be phthisis, this case must have been incipient), in which such a peculiar combination of physical signs exists, and on the other hand, the group of symptoms are equally opposed to such an opinion. In such perfect obscurity, indeed, would this diagnosis be involved, were it not for the philosophical observations of Dr. Stokes, that to arrive at anything like a true one would indeed be a matter of difficulty; but I do not think that it amounts to mere assumption, when we assert that, in a person presenting such a group of physical phenomena, in all probability the disease was not phthisis nor the result of pneumonic inflammation. To say what it is involves a difficulty; nor have I the opportunity of ascertaining. Was it one of the cases of interrupted cancer?

With regard to the second class, or that condition of the lung in which the cancerous matter occupies a portion greater or less of the lung, we are not unfrequently involved in very great difficulty, and are utterly unable to come to a satisfactory conclusion, and, as has been remarked, we are or can be only guided by the signs of solidity, and must rely for assistance on the other collateral circumstances of the case. But the case is very different when the whole of one lung becomes involved, as was first described at one of the earlier meetings of the Pathological Society of Dublin, by Mr. Stokes. In his case, and I believe the only one on record, the whole lung was most perfectly and completely disorganized, and connected into a vast mass of cancerous matter, the bag or sac of which was formed by the thickened and now dense pleura. The phenomena resulting from such a state of parts being perfectly novel, necessarily rendered the case very obscure, and all that Dr. S. did here was to say, "it is a disease which I never saw before, and is perfectly new to me." The post-mortem appearances, however, completely bore out the physical signs, and should such a case ever occur again

there would be no difficulty in pronouncing an opinion as to its real nature. To avoid a lengthened account we shall be very brief in our narration of them, and without attempting to give the history of the case, which will be found in one of the late Nos. of the Dublin Journal of Medical Science. When the poor woman was admitted, the whole of the right side of the chest sounded dull on percussion, and distinct gurgling was heard in many portions of that side: this state continued for a day or two, and was succeeded by copious expectoration of puriform matter, and immediately the physical signs were tympanitic clearness of the whole side, and this alternation of signs occurred several times during the progress of the disease. Such cases are, however, of very rare occurrence, but in the event of their so appearing, I imagine the diagnosis to be easy, compared with the other forms of cancerous degeneration.

We now come to a much more important part of our subject, viz. the occurrence of cancer of the lung simulating aneurism. This might at first sight, and certainly with great plausibility, appear, to those unacquainted with the intricacy of the subject, an impossibility, but that such is nevertheless the fact is well known to any one in the least acquainted with physical diagnosis; and this is not only true as regards these tumors within the chest, but elsewhere; as, for instance, in cancerous masses circumscribing a large vessel, a case of which we will briefly mention by and by.

In these cases the condition of the contents of the cyst may be of such a nature as to receive faithfully the pulsations of the vessel passing through it, so that we shall have the diastolic pulse exactly presented; but there are also other cases again in which we have these pulsations more defined and following the course of the vessel.

It is in these cases more especially that the greatest obstacles to correct diagnosis exist; here the simulation of aneurism is so close, that especially as to the physical signs, the collateral evidence of any such aneurism being present must be exceedingly strong to warrant a conclusion of the nature of the case. Of these cases, however, we purpose speaking in a future communication.

[To be continued.]

## PECULIARITY IN THE TRANSMISSION OF HYDROPHOBIA.

*To the Editor of the Medical Gazette.*

SIR,

On the 20th of May last, two ewe sheep were bitten by a dog labouring under hydrophobia. One of them had two lambs at her side, which were allowed to continue with her for a fortnight after the bites were received. She was bitten and torn considerably about the head. The other also had one lamb (a ram) with her. She received one bite only, in the neck; it was, however, a very severe one. The lamb was allowed to remain with her the same time as the others. About six weeks after the bites had been received, the first named ewe evinced the following symptoms:—she was observed often pawing and striking the other sheep, like a ram—a very uncommon circumstance in a ewe; she was convulsed at intervals—she continually turned her head to her side in a convulsive manner; the bowels were very much constipated, and what little came from her was of a red colour; she refused all food. These symptoms continued, increasing in violence, for about eight days, when all hope of her recovery being abandoned, she was destroyed. A day or two afterwards, the other ewe became affected in the same manner, and the whole circumstances of the case were precisely similar to those of the former. She was killed on the seventh day. Nine or ten days after the death of the last sheep, the ram lamb was attacked in the same manner as its mother; it was, however, much more violent, butting at the other sheep, and at the hurdles, and at any thing else that came in its way; it was continually tearing the wool from its side. It expressed no uneasiness at the sight of water in a ditch, part of which was inclosed along with it by some hurdles. It was killed a week after the first appearance of the symptoms. The other lambs were attacked at the same time, and in a similar manner, as the ram, but were not so violent. They were, however, killed together, as their cases appeared equally hopeless.

The great singularity which is observable in the cases is, that *the lambs became rabid merely from sucking ewes*

which had been bitten by a mad dog, for the lambs were removed from them a month before the ewes became affected. The lambs were all carefully examined, in order to discover any bite they might have received, but not the slightest scar could be discovered. The same dog bit a number of other sheep in the neighbourhood, the greater number of which died of hydrophobia. He bit a man, also, in the hand, but excision was performed, and he has hitherto done well.

No attempt was made to relieve either the ewes or the lambs.—I am, sir,

Your obedient servant,

S. H. STEELE.

## ANALYSES AND NOTICES OF BOOKS.

—  
“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

—  
*The Vegetable Cultivator: containing a plain and accurate description of all the different species and varieties of culinary vegetables; with the most approved method of cultivating them by natural and artificial means, and the best modes of cooking them, &c.* By JOHN ROGERS, Author of “The Fruit Cultivator.” London, 1839. Small 8vo. pp. 343.

THIS neat and compact volume contains instructions as to the best method of cultivating sixty-eight vegetables, which are alphabetically arranged from artichoke to winter cress; and twenty-five physical herbs marshalled in the same manner, from angelica to wormwood.

If ever a man was qualified to teach, by length of experience, that man is our author. Even the most grey-headed reviewer of our fraternity, who may have driven the censorial quill for some half century or so, would shrink from disputing with a gardener who knew Philip Miller, and who has cultivated cucumbers for seventy years. His critical infallibility would desert him! Most curious it must be for a nonagenarian to look back over so vast a gulph of time, and passing over the comparatively modern period (a mere yesterday to him) when vegetable marrow and Wellington boots were struggling into existence, to go back through a series of happy decads to the days of

short indispensables and Junius's Letters! When ladies wore saques and hoops and powder; when gentlemen pinked one another with swords, and took off their hats in the streets; when ceremony was polite, and three o'clock dinners fashionable, then did John Rogers gain prizes for melons, and soar high above contemporary pea-forcers!

Nor has time abated the edge of his zeal, nor diminished his love for gardens, frames, and hot-beds.

“Agnoscit veteris vestigia flammæ.”

“The staunch old gardener still remains the same,  
His frame yet knows the vivifying flame.”

ANON.

Our author is naturally sometimes a praiser of the days of old; the marrow-fats of the *bon vieux temps* still dwell in the greenest spot of his memory, and melons long since departed, melons that won prizes A. D. 1780, still spread their fragrance over his pages\*!

Yet we would not have our readers suppose that the author lives only in the past, or imagines vegetable excellence to have been stereotyped in the eighteenth century. Quite the reverse; he is well aware that the science of the kitchen-garden, like all others, is progressive; and he tells of early Warwick peas, of early racehorse peas, of Flanders spinach, and of Normandy cress, as well as of the old-established favourites. There is a freshness about his subject which comes home to the bosom of every uncorrupted reader, and the author treats it in a congenial spirit. In good truth, his very age is a proof of no inconsiderable merit; the peevish, the intemperate, the ill-conducted, do not live to ninety†. He gives, too, many receipts for dressing vegetables. For example:

\* We are not quite sure that the author is right when he says, “In France, and some other parts of Europe, the melon is frequently served up at dinner as a sauce for boiled meat,” (p. 160.) In France it is a common *entremet*, or intervening dish, during dinner, but we do not recollect it as a sauce. In an amusing French work, “*Les Français: Mœurs Contemporaines*,” a duchess is described labouring under *anglomanie*, who can eat only *giblet-soup* or bread sauce; her husband can get melon at the desert alone; and to have peace in the house, he is obliged to eat it with rhubarb.

† Like a true gardener, John Rogers is of wholesome tastes, and thinks of beauty with the orthodoxy of an artist or a physician. There is, as every one knows, a fellowship or analogy in preferences; and as perverted relish calls perverted relish brother, so good taste of one kind is a pledge for the presence of another. Your marrowless town rake, withered in heart and frame, like a pale, and pasty, and almost anasarous complexion; thinks the glow of health disagreeably rustic, and extols the sickly graces

"The second dish, which was a favourite and fashionable one some fifty years ago, is made of the sugar pea, when young, dressed with the pods, requiring only the outside edges to be stripped off. These are to be put into a stew-pan with some good gravy, thickened with flour and butter, with a little mace, ginger, and nutmeg, and allowed to stew gently until the pods are quite tender, as they are unlike any other sort of pea, not having a tough coating inside the pod. The sugar pea, dressed after this manner, forms a most delicate side dish at the table." (p. 224.)

In the next edition of the book, for next edition there must and will be, we could wish to see the French methods of dressing vegetables introduced; the *petits pois au sucre*, and *pommes de terre à la maître d'hôtel*, for example, should by no means be pretermitted. Like frank Meg Dods, whose Cookery book is doubtless in the hands of all our readers, we allow, to "save trouble," as she says, that the French are the best cooks in the world; and the sooner this truth is universally admitted, the better. We strongly recommend Mr. Rogers' Vegetable Cultivator to every one who has a garden. The book makes one long to have half an acre, or so, of one's own, Kewward, or, not to travel so far, down there by Chiswick: *colat hortum ter vel quater in septimanâ* would not be a bad prescription for many a hypochondriac; he might eat the stalks of his rhubarb, instead of the root.

*Plantæ Utiliores. Illustration of Useful Plants, employed in the Arts, Medicine, &c.* By Miss M. A. BURNETT, Sister of the late GILBERT THOMAS BURNETT, Professor of Botany at King's College, London. No. 1, London 1839. 4to. pp. 6. Two coloured plates.

THE following extract from the prospectus will show the object of this work:—

"The letter-press will consist, as occasion may require, of extracts from the most popular authors, introducing

of Lurida. John Rogers prefers, as we do, the cheek of Callipareia made up of damask roses and sunny sides of peaches, with the flashing glance, that might befit a Hourii just descended from Paradise, the black-eyed reward of some true believer—or, as he expresses it, "a fine bloom on the cucumber will be essential, this ornament being always admired both in the animal and vegetable kingdom." (p. 93.)

portions of the unpublished MSS. of the late G. T. Burnett, with the scientific and English names of the plants. The Linnean Class and Order will be given, but the descriptions will be founded on the natural arrangement. The object of the present publication will be, to give accurate and faithfully coloured figures of plants, particularly selecting those used in the arts, medicine, and for ornament, or which are interesting either for their beauty or associations."

The present No. contains two beautifully coloured plates representing the tobacco plant (*Nicotiana Tabacum*), and the blue passion flower (*Passiflora cærulea*.) This work has evidently been a labour of love with Miss Burnett, who is not only a most skillful artist, but is by profession a colourer of drawings and maps; and has consequently been able to lavish more finished beauty upon her designs than could be expected in a work of treble the price. The remarkably small sum for which it is sold will bring it into the drawing-rooms of hundreds whose fortunes are not equal to their taste; and the man of letters will be gratified by the extracts with which the plants are illustrated. The account of tobacco is particularly entertaining, and includes a part of the declamation of James, the author-king, against the use of this too fascinating weed; the passion-flower is commented on in a passage from Hervey, the celebrated author of the *Meditations*.

We cannot doubt that this work will meet with a large sale; he carries off every vote, says Horace, who mingles the useful with the sweet; and this is Miss Burnett's case.

## THE NEW POOR LAW.

SOME time has now elapsed since we discussed this painful subject; but it is of such great and growing importance, of such paramount interest to every lover of the commonwealth, whether a

mere citizen or a practitioner of physic, that we should be censurable if we continued to pass it over.

A hope of better times begins to dawn ; for it is now seen by all the more discreet partizans of the new law—by all, in short, who do not add utter blindness to perfect selfishness, that one of the most grinding provisions of the Act must be given up ; it is acknowledged that, during seasons of distress, it is impossible to refuse out-door assistance to the hungry and the naked.

A benevolent clergyman (the Rev. Mr. Bull) advised his starving parishioners to take the assistance so sneeringly proffered them, and enter the lurid asylum of the Union Workhouse ; and had his advice been followed, the House of Correction for poverty must soon have been filled, and consequently out-door relief must have been given, even according to the principles of the framers of the Act. But whenever a hard season arrives—when ever employment is scanty or ill paid, with the 4 lb. loaf at elevenpence, the poor houses will be crowded ; the irresistible instinct of nature driving multitudes to submit to the slow process of starvation within those sanctuaries, rather than undergo the acuter form of atrophy without.

We wish, however, that this remedial step had been immediately taken, at the suggestion of Mr. Bull ; and that we had been sooner blessed with the virtual repeal of one of the worst clauses of the Act.

The promoters of the new measure hoped, of course, that no one would be found to give the poor assistance by word or deed. In one of the Commissioners' annual reports, a Malthusian of Bath complains bitterly of certain charitable ladies, whose alms prevent an aged pauper from entering the Bathonian *ergastulum* ; and as for a philanthropist teaching the indigent how to

fill the workhouses, and thus obtain out-door relief for the overflowing majority, this is indubitably flat rebellion against their majesties of Somerset House, and should be punished under some nice sweeping clause as an obstruction of the Act.

The medicines for the poor, they might add, are to be found in the cellars and the kitchens of the rich ; and the great proprietor or opulent farmer can rarely be so unmindful of what he owes as to leave the cultivator of his fields to apply to the community for relief. For, if the instinct of equity is not entirely extinguished in his bosom, he must be aware that the pittance which he gives his labourers under the name of wages is far from a true adjustment of the account between them. The smallest possible sum which competition forces the ploughman to accept is not the just reward of his toils ; nor, if we add to his weekly stipend the sums expended for him when sick and decrepit, will the total amount to any adequate recompense. Or if this picture of good-humoured justice be supposed to be too highly coloured, and more like the anticipation of some happier age than any thing possible in the present one, it will at least be allowed that similar duties devolve on the community at large. If we cannot expect each landholder to consider those who gather in his harvests, and swell his rent-roll, as the poorer members of his family, at least we should hope that when the care of the indigent husbandman is transferred to the community, he would be treated not as a criminal, but a benefactor. Every individual in the army and navy, every public functionary, whether high or low in rank, has a right to a pension after a fixed length of service. Their pay, generally speaking, is not large, and it is justly thought that the pension and the pay combined are not more than a fit reward for their

labours. It is thought better to grant a pension, than to give higher pay, and trust to the chance of the receiver's saving a part. Now to the half-fed husbandman standing at the bottom of the social scale, and exposed to competition in its most intense form, competition sharpened by hunger at his very door, this mode of dealing is peculiarly applicable. The daily labour of twelve hours rewarded by the coarsest clothes, the cheapest lodging, and insufficient meals of bread and potatoes, may surely claim an annuity in old age, without wounding the most sensitive Malthusian in Belgrave Square.

But if those whom destiny has placed at the top of the social scale, cry out to those at the bottom that they are to bring up their families on eight shillings a week, and save something for a rainy day, out of the superfluity; or if they add one gross unnatural insult to another, and tell the poor to wear away their lives in celibacy, we frankly confess that the optimist representations of our moralists will have lost their force and the truth. It is plain, in this matter of the forced celibacy of the poor, that there is a glaring bit of silliness at the bottom of the utilitarian selfishness—an illustration of Coleridge's remark, that "a rogue is a round-about fool, a fool in circumbendibus."

For if only a few hundreds or thousands of our husbandmen followed the profligate advice given them, and abstained from marriage, there would be merely a few additional hundreds or thousands of licentious bachelors and spinsters; but if the poor generally followed this destructive counsel, so as to gratify their advisers by a visible falling off in the population, the rich would be losers. The most callous economist with universal anæsthesia, save in his pocket, would find that wages would rise, that lands would be untilled, and he would learn, too late, that the industrious and

ill-used labourer carried five sheaves into his master's barn for one that he consumed himself. Give these frigid philosophers rope enough, and they would hang themselves; but the worst is, they would hang many honest people at the same time.

According to Dr. Bureau-Riofrey, in the year 1558 our population was so dense that the poor were not allowed to marry before thirty\*. We candidly confess that we never heard of this law before; and what with plagues, sweating sicknesses, and constant complaints of depopulation, it is the last statute we should have expected to hear of in the days of Mary or Elizabeth. Nevertheless, it may have been so; parliament may have been seized with a sudden horror of shabby weddings and portionless children; and this paroxysm of the fear of increase may have stood out amid the general tranquillity on the subject, like a rugged rock in an unruffled stream. If Dr. Bureau-Riofrey is right, the Commissioners will rejoice; and while they praise the good old times, will be tempted to recommend a similar measure to the collective wisdom of the nation—perhaps substituting 40 for 30, in accordance with the progress of knowledge.

Another coincidence between that age and our own deserves to be noticed. When the abolition of the monasteries deprived the poor of their accustomed resources, hardly any attempt was made to provide a substitute. They cried for bread, and the law gave them a stone. Statutes of the most revolting severity were passed against beggars and vagabonds; but hunger will break through stone walls, and even the gallows could not quell it. Accordingly, that famous statute was passed in Elizabeth's reign for the relief of the poor, which in spite of all its defects, whether theoretical or

---

\* *Londres ancien et moderne*, p. 90.

practical, has raised the condition of the labouring classes in England beyond that of any other country in Europe. The poor have now again been deprived of their stay—a second abolition of monasteries has taken place for them, and it is proposed to give them a rural police. But we predict that this will be insufficient to keep down the complaints of the famished; and some milder remedy must be sought. Either we must have a mitigation of the law, involving the abolition of all its harsher clauses, or emigration must be encouraged on the largest scale, and aided by the most liberal expenditure of the public funds.

We may remark, too, that, as in olden times, the crowd of the discontented did not consist merely of the starving poor, but included the most desperate criminals, who were glad to engraft their predatory habits on a popular cause, so now the burglar or the pickpocket will occasionally join the throng of complainants, and give himself the air of injured innocence. In some cases, no doubt, motives are mixed, and indignation at the oppressor is superadded to previous irregularities. The other day, a man named William Watts was convicted at the Norfolk Quarter Sessions of shooting cattle, and sentenced to transportation for life. He acknowledged the justice of the sentence, and said that the cruel poor laws, and the rates and taxes now imposed on the labourer, drove him to dishonesty. "He would not see his children starve, while he was called on to support full-fed relieving officers, and other folks connected with them and the unions."

We compared above the new act to a declaration of war; and, as in other wars, it will often happen that the subaltern workers of mischief venture on acts of which their commanders cannot publicly approve. The masters of workhouses, relieving officers, and other small fry, play very fantastic tricks. They know that they are to squeeze,

pinch, economize most subtly, shave most closely; and how to do all this, and yet preserve some regard for the decencies of life, puzzles them, as it naturally might. In translating the elegant insinuations of their masters into their own rude dialects, they fail, and sometimes get a rap on the knuckles.

At the Bungay petty sessions a young man was lately charged with robbing the Wangford Union of a suit of clothes, and going out of the poorhouse without leave. It appeared that the Union clothes had been given him in place of his own; but instead of being admitted into the workhouse, he and two others were taken to the criminal gaol, and put into a filthy cell in which were two men ill with the itch; "he thought that he had no right to be used in that infamous manner, and, seeing a means of escape, he got out, but not before he caught the disorder. On the next morning he sent his father with the Union clothes to the workhouse, but the master refused to take them, or give up his own. The magistrate asked the workhouse-keeper if this statement were true, and he answered that it was; he did not think he had done wrong by putting a pauper into gaol with people who had the itch. The bench, after expressing their disgust at the way in which the defendant had been treated, immediately dismissed the complaint\*."

*General remarks.*—*Fracture extending into the knee joint.*—*Varicose veins.*—*Use of twisted sutures.*—*Case of phlebitis.*

GENTLEMEN,—On the occasion of delivering my first clinical lecture this session, I should not be discharging my duty were I not to express to you my own conviction,

---

\* Times of Oct. 14, from Suffolk Chronicle.

that every surgeon of a public hospital ought to deliver clinical instruction, so that students may derive, from the various interesting cases continually presenting themselves, a practical acquaintance with their profession. Were this praiseworthy custom neglected, the hospital fee would be paid merely for the privilege of walking into the wards, and then out of them again, without the purpose of attendance on hospital practice being fulfilled. Strictly speaking, *clinical observations* are those made at the bed-side of the patient, while the case is in the presence both of the surgeon and the students; and so far as this plan can be adopted, with due regard to delicacy and the feelings of the patient, it has advantages. Who can doubt that every remark offered by the surgeon, while the disease is actually in view, will not only be more likely to be correct, or to correspond to the real state of it, but also better calculated to make a more durable impression? The surgeon is obliged, as it were, to keep within the limits of accuracy, by the facts and evidence before other parties as well as himself. It is expedient, however, that, in many instances, the patient should not hear all that is said about him. It would frequently have a pernicious influence on the disease which he is labouring under, if we were to disturb his mind with remarks on the dangers to which he is exposed, or on the likelihood of his having no chance of recovery, except by means of a painful and hazardous operation. Neither is it always right, even with reference to the patient's own welfare, that he should be made exactly acquainted with the medicines which he is taking. For these and other reasons which might be specified, it is deemed proper that the particulars of certain cases should be explained and commented upon in this theatre.

*Fracture of the thigh bone, extending into the knee-joint, followed by large abscesses, disease of the joint, and necessity for amputation.*

When I had the pleasure of meeting you last Saturday, you heard many of the particulars of the case of Edward Lyon, whose limb was removed on that day for a fracture of the thigh-bone, extending between the condyles into the knee joint, and complicated with extensive abscesses in the limb, and urgent hectic symptoms. After having tried for five weeks to save the limb, I was sorry to perceive that the only chance of saving the man's life depended on amputation. But even the result of this was considered to be extremely doubtful, not only on account of the very enfeebled state of the patient, but because a considerable portion of the cyst of one abscess, at the inner part of the thigh,

reaching nearly to the groin, would be left, and still be a source of a profuse discharge, unless the limb were taken off near the hip, which would have subjected the poor fellow to yet greater perils; the severity and danger of a thigh amputation being in a great measure in proportion to the nearness of the mutilation to the trunk.

Another discouraging reflection was, that there would also remain after the operation an ulcer, three inches in diameter, situated over the sacrum, and occasioned by the pressure of the bedding. These various circumstances were bad enough; yet having had opportunities of seeing amputation frequently save patients who were in a still more reduced condition than this patient, I proposed the operation, to which, after two days' hesitation, he made up his mind.

After a mature consideration of this case, I have arrived at the conclusion, that it was in truth, originally, not merely a fracture extending into the knee-joint behind the patella, but a compound fracture of the thigh; and that what is described in the case-book as a slight graze, must have been an opening formed by the very sharp end of the upper or lower fragment of bone; for otherwise, I think that the abscess which followed would not so soon have found an outlet at this point, which, on the first removal of the bandages, was seen converted into an opening, from which a thin brownish matter was discharged. The manner, also, in which the accident took place likewise corroborates this inference; for the man fell with immense force, as he was carrying a female who had fainted, down some steps out of a concert-room; and consequently the violence of the fall was increased by her additional weight.

In operating, I selected the method in which an anterior and a posterior flap are formed; for though lateral flaps seemed best calculated to facilitate the escape of the matter, which was likely to be abundant in a case like this, where a portion of the cyst of an abscess was unavoidably left behind, yet, having learned from experience that when lateral flaps are made in the thigh, that the bone is much disposed to protrude at the anterior angle of the wound, I preferred the other method. You will immediately perceive why there is a tendency to protrusion of bone when lateral flaps are made; it evidently depends upon the following circumstances: first, upon the nearness of the end of the bone to the front angle of the wound; secondly, upon the weight of the flaps themselves, which, as the patient lies in bed, necessarily gives them a propensity to incline backwards. To these two considerations must be added the

effect of the occasional action of the psoas and iliac muscles in drawing the femur forwards, which increases the tendency to protrusion of the end of the femur when the flaps are lateral, but has not the least influence in this way when the flaps are placed anteriorly and posteriorly.

Some time ago I amputated a thigh in this hospital with lateral flaps, and I am sure that if it had not been for the great skill evinced by Mr. Chapman, my late house-surgeon, in dressing the stump and supporting the flaps well, there would have been a protrusion of the end of the bone; but fortunately this was avoided, and the man, a butcher in this neighbourhood, has a firm, well cushioned, excellent stump. M. Velpeau tried the method with lateral flaps; but the patient was not so lucky as mine, for the bone protruded, and the stump went on so badly that the patient sunk. Hence, M. Velpeau declares that he will not adopt this plan of operating again. In general, the anterior flap should be longer than the posterior; but, in our case, the latter was made rather longer than the anterior one, because it was desirable to remove with the limb the parts in front of the thigh, in which several incisions had been made, and from which the matter had partially been discharged during the treatment antecedent to the operation. The reasons for generally forming the anterior flap longer, and the posterior one shorter, are, that the latter may not make too extensive a pouch for the lodgment of matter; for it is manifest, that from this part of the wound the pus cannot so readily discharge itself as it can from beneath the anterior flap. Another advantage is, that if the bone be well covered with the anterior flap, there will be little risk of a protrusion of the end of the bone, followed by necrosis and tedious exfoliations, or even by the necessity of another operation to get rid of the dead bone.

You will observe, that in this hospital the wound is not closed directly after the operation, but merely covered with lint or linen, wetted with cold water. The advantage of this plan is, that time is afforded for all the bleeding to cease before the surfaces of the wound are brought together; and, by this means, they are not so likely to become separated again by effused blood, as when the stump is dressed in the usual way. If the wound of amputation be dressed while the oozing of blood is going on, the cavity of it is soon filled with clotted blood, which not only acts disadvantageously by mechanically separating the surfaces of the wound, but is infinitely less fit, as a medium of union, than coagulating lymph or fibrin,

because it is not, under these circumstances, organizable like the latter plastic substance. I may say, in fact, that it rather acts as an extraneous matter, unfavourable to the adhesive inflammation, or union by the first intention, than as the source of any good.

The stump was therefore not closed till the evening with isinglass plaster. But besides the considerations in favour of this method which I have been explaining, there is another that has some influence with me: if any hæmorrhage take place within the first few hours after the operation, the bleeding vessels can be secured without subjecting the patient to all that suffering which is necessarily produced by removing the numerous straps of adhesive plaster employed in the old and still too common practice, and by then opening the stump again. In fact, in our case, two or three small arteries did bleed in the course of the afternoon, but were immediately secured with the utmost facility, and without the slightest disturbance of the wound imaginable.

Four hours after the operation, in consequence of the patient being seized with vomiting, it was necessary to give him a draught containing two minims of dilute hydrocyanic acid. Notwithstanding this, the vomiting of a black bilious matter went on till after midnight, when it finally ceased. Since then the patient, with the assistance of the muriate of morphia, given in the dose of gr. j. every evening, has generally passed very comfortable nights; he is free from pain, and eats and digests his food as favourably as can be expected.

On the 9th, however, his pulse was so weak and frequent, and his countenance so bad, that he was considered to be in a dangerous condition. To-day he is quite changed for the better, and the discharge from the stump is diminishing, and of better quality.

The knee-joint, which is put on the table for your inspection, shews the extension of the fracture into the joint, the pointed and irregular projections of the broken bone, and the absorption of the greater part of the cartilage from the posterior surface of the patella, the condyles of the femur, and head of the tibia. These facts attest the hopeless condition of the patient had amputation not been performed. The progress of this severe case, be it favourable or unfavourable, I shall again notice.

*Varicose veins of the leg, treated with the twisted suture.*

Gentlemen,—This practice, as you have had opportunities of seeing, continues to be pursued in this hospital.

John Griffiths, æt. 44, a mason; a tall muscular man, of intemperate habits, and habitually constipated, has been troubled with varicose veins of the lower extremity for fifteen years. As a consequence of this diseased state of the veins, he also had a large and obstinate ulcer on one of his legs, which, however, healed up some considerable time ago, and has not broken out again. But, below the inner malleolus, there is another ulcer, that has continued about three months. The branches of the great saphænal vein, as usual, are those principally affected, and they exhibit a tortuous, knotty, and swollen appearance, very conspicuous when the man stands up. In consequence of this state of the veins, a good deal of aching pain is always experienced in the limb after exercise.

For the purpose of obviating the disposition to ulceration in the leg, and relieving the pain in the limb, caused by work or exercise, I have tried the application of twisted sutures to the enlarged veins.

Oct. 1, I began with a single one, which was placed under the great saphænal vein in the upper third of the leg. While the man stood up upon his bed, so as to render the vein large and manifest, it was taken between the forefinger and thumb, and a steel sharp-pointed pin, about three inches in length, passed under it. Some thread was then twisted firmly round the ends of the pin, and the redundant portions of the pin cut off with a small pair of bone forceps.

After the pin had remained about eight days it was withdrawn, and two more twisted sutures applied to an enlarged portion of the vein lower down. The progress of the case is now open to your observation.

When this practice was first adopted on the continent, the pin was sometimes merely passed through the vein, and no thread twisted round it at all. Afterwards the pin was introduced under the vein, and the twisted suture was employed, and allowed to remain until thrown off by ulceration. This was tedious, and sometimes left a painful and obstinate sore.

Mr. Liston was led, therefore, to try the improved method of removing the pin and the suture altogether as soon as the ulcerative process had fairly commenced; so as to expedite the cure and avoid the formation of an ulcer. This is the plan now pursued in the case before us.

The following advice I venture to offer you on the treatment of varicose veins with the twisted suture. Do not hastily resort to it, or any other operative measure, in any unfavourable state of the constitution; for, if you do, your patient may be attacked with erysipelas, or severe abscesses, or, what is more formidable, with phlebitis, and the result be fatal, an in-

stance of which I will relate. The case occurred very recently in this hospital.

*Ulcer of the Leg, accompanied by varicose veins, for which twisted sutures were applied.—Phlebitis, and death of the patient.*

Edward Ranger, æt. 59, by trade a dyer, and a man of intemperate habits, admitted June 19, 1839, with an ulcer of considerable size on the right leg, and many tortuous varicose veins connected with it. The sore was at first covered with the water dressing, and after the man's bowels had been cleared out with a dose of calomel and senna mixture it was determined to try to cure the varicose veins with twisted sutures, and three were at once made; one about four inches above the knee, and two others below it.

June 23.—Severe pain in the situation of the sutures.

25th.—The sutures below the knee now cause no pain, but that in the thigh still keeps up great suffering, and has brought on swelling.

26th.—Sleepless night, and appetite bad. Upper suture withdrawn.

Two grains of calomel, and one of opium, every night. Water dressing applied.

27th.—Very severe pain in the left shoulder and arm. Two or three shivering fits, each of half an hour's duration, succeeded by heat and other febrile disturbance.

28th.—Shoulder and arm still exceedingly painful. Another shivering fit this morning. Considerable redness and hardness at inner side of the thigh, in the course of the great saphænal vein. Pulse frequent. Tongue furred.

Saline antimonial mixture every four hours. Calomel and opium continued. Fomentations.

The indisposition being severe, the two other pins were removed.

July 8.—Until this date, the case went on without any material change, attended with great pain in the shoulder and arm; but now the man was attacked with profuse diarrhœa; the pulse became weaker and more accelerated, and the tongue thickly covered with a dark yellow fur.

Pill omitted. Chalk mixture, with opium, prescribed, and a liniment for the painful shoulder.

10th.—Diarrhœa stopped. Debility increased. Pulse small and quick. Brown and dry fur on the tongue.

Mixture discontinued. Wine and porter allowed.

12th.—Chalk mixture required again. Abscesses in the thigh in the situation

where the upper suture had been applied. Openings made for the discharge of the matter. Poultice.

15th. — Pain in shoulder unabated. Bowels yet too loose. Pulse fluttering and irregular. Tongue coated with a black fur.

17th. — Delirium. Diarrhœa, and extreme anxiety of countenance. Death at 7 P.M.

*Section Cadaveris.*—Surface generally of a yellow tinge. *Thorax*: lungs extensively adherent to the parietes of the chest, especially the left, and the adhesions not of long standing. Tubercular deposits in various stages within the lungs. In the pericardium three ounces of serous fluid. Heart somewhat enlarged and softened. Osseous deposits in the semilunar valves of the aorta, and under the lining of left ventricle.

*Abdomen.*—Left kidney contained pus. The right iliac vein also had pus in it as high up as the vena cava. The crural vein was occupied by purulent matter, as well as the popliteal.

A large quantity of purulent matter was found under the fascia lata and in the intermuscular cellular tissue. The right hip and knee-joints both contained pus, and within the left shoulder-joint, and in the textures external to it, pus was likewise detected.

REMARKS.—Gentlemen, this case illustrates many interesting points.

1. The usual commencement of phlebitis between the second and twelfth days after the injury and suppuration of a vein.

2. The usual symptoms and perils of *suppurative* phlebitis,—anxiety, prostration of strength, repeated rigors, quick feeble pulse, yellowness of the skin; pain, inflammation, and abscess, in one or several of the synovial cavities or viscera. In our case you find pus was formed in the kidney and in various joints. Dry, brown or black tongue; in latter stage diarrhœa and delirium. Great hardness in the course of the inflamed vein. Abscesses in the thigh.

3. The general fatality of *suppurative* phlebitis when the pus gets directly into the circulation, as it were, unprepared by the action of absorption for such transmission.

4. The inefficiency of any treatment yet suggested, after the effects of the admission of pus into the circulation have commenced.

5. The case calls our attention to the question, under what circumstances is the attempt to cure varicose veins of the leg justifiable by any means attended with a risk of exciting this formidable disorder?

I should say, certainly not, if the varicose veins, and the ulcer connected with them, admit of relief from other plans, and are not producing severe annoyance, nor are generally interfering with a person's endeavour to gain a livelihood.

Then, if this kind of twisted suture be adopted, ought we to apply it at once in several places, or only in one, repeating it afterwards, if another is necessary? The latter method is probably the safest. In particular, I advise you not to adopt the practice at all in unfavourable constitutions.

## WESTMINSTER HOSPITAL.

### *Infiltration of Urine into the Scrotum and Cellular Tissue of the Abdomen.*

[Reported by Mr. RICHARD YOUL.]

THOMAS LOCKWOOD, aged 39, was admitted 5th Sept. under the care of Mr. Anthony White.

He was of middle stature, and a lymphatic temperament. The scrotum was tumefied, and of a purple colour. This dark colour extended over the hypogastric region. The patient complained of a dull heavy pain in the scrotum, and he could not move his body without much suffering. His pulse was 64, wiry; his tongue furred; and his countenance anxious.

He had been a grocer, and not very sober in his habits. He had successive attacks of gonorrhœa, which ended in producing stricture. The stream of urine gradually diminished in size, and yet no effort was made to remedy the evil.

On Monday the 23d, when making severe muscular efforts to expel his water, he felt suddenly as if something had burst in the right groin. This was followed immediately by the occurrence of pain. He went to a dispensary, where an attempt was made to pass the catheter, but in vain. Next morning he came to the Westminster Hospital.

The patient was first seen by Mr. Hale Thomson, who ordered him a warm bath, at 100° Fah. Mr. White was then sent for, and attended with his characteristic promptitude. He made an incision through the tumefied scrotum, on each side of the raphe, downwards, as far as within an inch of the anus. A copious exudation of serum took place. Thirty leeches were applied to the abdomen, and twenty minims of Battley's sedative liquor of opium given every four hours.

3 P.M.—The leeches bled freely. The bleeding was encouraged with warm fomentations. The pain is less.

9 P.M.—The patient seen again by Mr. White. He had not passed any urine, and a bougie could not be introduced. More incisions made in the scrotum. The remedies to be continued.

25th, 9 A.M.—The patient has slept but little during the night. He expelled a little urine, *guttatim*, this morning. The pulse is 72; the bowels freely open.

1 P.M.—Countenance less anxious; pulse 68; tongue clean. The abdomen, however, retains its darkened colour. Mr. White ordered the medicines to be continued.

9 P.M.—Great anxiety of countenance; pulse 84, small and compressible; intense headache; the tumefied parts of a darker purple hue; urine has dribbled away in the same scanty way as already stated. He appears sinking.

26th, 10 A.M.—The patient very much worse in all respects. Headache augmented; bowels confined; has not slept all night. A wild and anxious expression.

12 o'clock.—Mr. White saw him. The abdomen threatening to slough, a free incision was made upwards from the pubis, to the extent of about three inches. Ordered a draught of castor oil and tinct. sennæ. Fomentations to be applied all over the abdomen and scrotum. On examination, the whole cellular covering of the abdomen felt hard; the surface was very insensible also. Pulse 64, more full; the discharge of urine still very small. The opiates discontinued.

9 P.M.—The man seen by Mr. White and Mr. Hale Thomson. Another incision made in the affected part, at a right angle with the previous cuts, some inches in length. After a little time, a small quantity of urine flowed, *per urethram*, in a thin stream. At midnight the countenance was less anxious; pulse 64, regular. Fomentations applied at intervals.

27th, 10 A.M.—The bougie No. 2 introduced, and a large quantity of urine drawn off, affording signal relief to the patient.

12 o'clock.—Has slept well; pulse 60; no headache; looks much better altogether. The incision is beginning to slough. To have fish diet.

20th, 10 A.M.—He is much better, and has had a good night. Bougie No. 3 passed. The cellular tissue is becoming soft, and healthy pus is secreted.

29th, 9 A.M.—The bowels being confined, an aperient is ordered. He is improving.

30th, 10 A.M.—Catheter No. 4 introduced.

Oct. 2.—No unfavourable symptom has occurred. The dead cellular tissue has been removed with the forceps. Light poultices applied. Mutton chops permitted. No. 7 bougie introduced.

4th.—Progressing. Placed on full diet. The incisions healing.

8th.—Patient ejects his urine better than he has been able to do for the last ten years. The catheterism is continued.

16th.—Rapidly convalescing.

#### *Application of Knox's Revolving Invalid Bedstead.*

On Sunday, the 13th inst. Mr. White and Mr. Thomson made trial of Mr. Knox's apparatus, on the person of Ellen Ridd. She is a young woman, aged 23, who has been brought up as a shopwoman, and employed in that capacity from an early age. She has had, consequently, a great deal of standing. Three years ago she became affected with a general sense of debility, and pain in the middle of the spine. She continued her avocations for a year, receiving advice and medicine from Mr. Toogood, of Bridgewater, the town in which she resided. Unfortunately she derived no benefit from the line of treatment adopted.

Two years ago she was admitted to the Westminster Hospital, where she was immediately laid recumbent. She has remained in that position ever since, almost without intermission, but without deriving any benefit from it. She has at present a curvature in the antero-posterior direction, the legs are contracted upon the hams, and the thighs upon the pelvis. She is a little delicate woman, of a very fine complexion, and a very phthisical appearance. When fixed on Mr. Knox's bed, and laid prone, a long and careful examination of the vertebral column was made, without producing pain or inconvenience to the patient. It affords her much relief to have her head raised and the feet depressed, and this position, at any angle from the vertical to the horizontal line, may be maintained for any period that may be agreeably borne by the patient. About two hours is the length of time she likes to remain in this position. The revolving motion she bears very well.

There appears to be no doubt but that considerable absorption of the bodies of several of the dorsal vertebrae has taken place, but the attendant surgeons are sanguine that with the assistance of this excellent apparatus they may succeed in producing a safe anchylosis of the affected vertebrae, and they are sure of obviating a large quantity of suffering, which the patient would otherwise inevitably incur.

The contraction which has been mentioned occurred very suddenly about seven months ago, and has remained inveterate ever since. The nurse states that the dejections are removed with perfect ease, and without occasioning fatigue to the

patient. She sleeps tolerably well, and maintains an existence not totally devoid of enjoyment. We shall anxiously watch the progress of the case, and report the result.

## REMARKS ON ENLARGEMENT OF THE TONSILS,

ATTENDED BY CERTAIN DEFORMITIES OF THE CHEST.

By J. MASON WARREN, M. D.  
Of Boston.

THE object of this interesting paper is to point out, by the exhibition of a number of cases, the certainty and ease with which the operation for excision of the tonsils may be performed with the present improved instrument, and the great relief always experienced by the removal of these organs when in an enlarged state. Whilst nothing original is intended by the author in his remarks on certain deformities of the chest which complicate this disease, they may serve to draw attention to the relation which exists between the enlargement of the tonsils and this affection.

In 1827, M. Dupuytren published a paper, Dr. Warren remarks, on the lateral depression of the parietes of the chest, consisting of a depression more or less great of the ribs on each side, and a proportionate protrusion of the sternum in front, accompanied by some antero-posterior curvature of the vertebral column. A portion of these cases occurred in children of a scrofulous habit, and were invariably accompanied by an enlargement of the tonsils.

The symptoms described by M. Dupuytren, as attending this disease, were habitual shortness of breath, and difficulty of enunciation. With infants there was great difficulty in taking the breast, the child being threatened with suffocation whenever the nipple was detained for any length of time in the mouth. During sleep, the mouth was kept habitually open, and the respiration accompanied by great noise, and frequently interrupted by frightful dreams and cries. "These symptoms," says M. Dupuytren, "may be increased so as to prevent the development of the vital functions, and cause death in the earliest period of life. When these difficulties do not induce death immediately, they may destroy life at a later period, either in preventing the child from taking the breast, or in so altering the nutrition as to prevent the development of the strength of the different organs; in this case death does not at once take place, but the child lives in a

miserable state of feebleness and emaciation, which deprives him of the greater part of his faculties."

In 1827, shortly after the publication of this paper, Mr. Coulson, of London, published some cases in confirmation of those given by Dupuytren, adding, also, three cases of his own, of a deformity of the chest different from that before described. "The external appearances of the chest," says Mr. Coulson, "in this second kind of deformity, are directly the reverse of those which we have just been considering. The sternum is hollow or concave anteriorly, the sides of the chest are very prominent, and the spinal column but slightly, if any degree altered from its natural shape; this is not so frequently congenital as the former kind, but frequently occurs in persons of a weak habit, who are narrow-chested, and stoop a great deal. The constitutional symptoms are very much the same as those attendant on the other kind of deformity." In the three cases appended to the paper of Mr. Coulson, and three of the four cases of M. Dupuytren, enlargement of the tonsils existed; but in none of them does it appear that removal of these organs was practised, although it is stated that in one or two of them the tonsils were so large as nearly to fill up the posterior part of the fauces, so that we are not enabled to judge of what would have been the change effected on the symptoms referred to the chest, had this operation been performed.

Within the last two years twenty cases have occurred in our practice, in which it was thought necessary that an operation for the removal of the tonsils should be practised: in nineteen of these cases the operation was successfully performed; in one case the tonsils projected so little into the throat, as to make it impossible to seize them with the instrument. The operation was temporarily deferred. Of these twenty cases, fifteen were children, or less than twelve years of age.

Of the fifteen children, eleven had more or less deformity of the chest, consisting, in the greater number, of a projection of the cartilages of the ribs forwards, with a considerable excavation of the sternum. In these patients very little curvature could be detected in the spinal column.

In the five adults, no alteration of the parietes of the chest was perceptible.

The symptoms occurring in these patients were as follows:

In every one of them was more or less difficulty in respiration, in many cases the noise being so great during sleep as to make it impossible for any person to sleep in the same room; the sleep was often disturbed by frightful dreams.

In many of the patients there was great difficulty of swallowing, liquid food being often regurgitated into the nostrils; in one case, no solid food could be taken without the previous use of a very powerful astringent. About half the cases were attended with severe constitutional symptoms.

In one case entire deafness was present. Some of the patients were liable to periodical attacks of fever; in one case, a child, five years of age, returning, latterly, as often as once a fortnight, and lasting three or four days. Eight of the fifteen children showed more or less marks of a scrofulous habit. Eighteen of the patients had both tonsils removed; the other patient being so much relieved by the removal of one tonsil, that it was unnecessary to have the operation repeated on the other side.

In about half the patients this operation was performed on both sides the same day; in the others a week was allowed to elapse before the other tonsil was removed.

In eighteen out of the nineteen cases, almost immediate relief was afforded to all the symptoms; in the other case no great relief was apparent, and this seemed to be attributable to the particular shape of these organs, the base being quite broad, and extending some distance down the throat; about half of each tonsil was removed. At the end of a short period, an appearance was presented as if they had been again regenerated; this arose from the upper and lower portions rising or curling up, as it were, after the apex had been removed. At the end of two years, this patient submitted to a second operation, followed by much relief, and is now in a fair way of recovery.

The operation, as performed by the present improved instrument, is instantaneous—not attended with much pain—in no case was there any considerable hæmorrhage—usually nothing more than a few mouthfuls of blood are discharged. The patients are able to return home and resume their ordinary occupations, as if nothing uncommon had occurred, a slight soreness only being experienced for the few following days.

We now proceed to offer one or two cases illustrative of the different symptoms of the disease, and may first select one which will present most of the symptoms occurring in the course of it.

W. of Newton, Mass. five years of age, November, 1836. For the last two years, this child has been troubled by an enlargement of the tonsils, first manifested by a swelling which appeared on the outside of the throat, and supposed by the parents, at the time, to be mumps. As the disease increased the patient gradually lost his

flesh and strength, and was subject to frequent sore throat, attended by febrile attacks, these latterly occurring as often as once in a fortnight, and lasting two or three days; his breathing at night was very difficult, and accompanied with much noise. The ear of one side was inflamed, attended with a purulent discharge; he was very sensitive to any loud music sounds. He is small of his age, thin, of an irritable disposition. The chest, on examination, is found to be much deformed, presenting that appearance called excavated sternum, it being very much depressed in its centre, and the ribs at their union with the cartilages elevated so as to form with them an acute angle.

The tonsils, on examination, are so much enlarged as to touch each other, and entirely obstruct the posterior part of the fauces; these swellings are distinctly felt and even visible on the outside of the throat, at the angle of the jaw; one of the tonsils was removed, and afforded immediate relief to all the symptoms. In the month of April following, some difficulty being experienced, the other was also excised. I saw the patient, August 3d, 1837, nearly a year after the first operation. From being a miserable child, and who, as is mother stated, to use her own words, "she had not the least idea of raising," he has become a fine healthy boy—has been perfectly free from difficulty of respiration, and no febrile attack since the operation.

The sensitiveness of the ear had diminished, and the deformity of the chest was much less obvious.

The object of his calling was from having experienced the day before some oppression at the stomach, which induces difficulty in the respiration; and his mother, fearing a return of his old disease, immediately brought him into town. The symptoms were explained, by his having passed a fortnight absent from home, where he had been allowed rather too much freedom in his diet.

The following is a case of a person of a more advanced age, in which deafness was produced by the disease:

B., aged 18—November, 1836.

For two or three years has been subject to frequent attacks of sore throat; for three months has had a purulent discharge from the right ear; is now quite deaf in both ears, so as to require to be spoken to in a very loud voice. It is for this deafness that he applies for advice.

On examination of the ears by the speculum, the tympanum on both sides was found to be in a perfectly sound state; on the side from which the discharge appears, the lining membrane of the ear is reddened, and covered by a purulent deposit. The patient bears all the marks of a

scrofulous constitution. The tonsils are found to be very much enlarged, attended with considerable redness of the back part of the fauces.

Astringent remedies being tried for a fortnight without effect, both tonsils were removed. On the following day he began to hear better; on the second day his hearing was perfectly restored, and sounds became even so acute as to be painful.

In a day or two the deafness returned, and lasted a week; he then recovered his hearing, and has remained perfectly well since. I have seen him lately, more than two years having elapsed since the operation; and he has experienced no return of his difficulty.

Jan. 1838.—A gentleman, twenty years of age, from the Western country, called on me with the tonsils greatly enlarged; he had been troubled with this affection five years, and has tried many applications without effect. For the last year he has been unable to swallow solid food without having first snuffed a great quantity of tobacco, which apparently caused sufficient contraction or insensibility of the parts to allow of the passage of the food. If the use of the tobacco was omitted for a single night, he found it difficult and sometimes impossible to swallow.

Both tonsils were removed at the same time; very little hemorrhage occurred, and the operation was immediately followed by great relief.

Miss J. twelve years old, from Maine.

This child, from infancy, has been suffering from enlarged tonsils; within a few years they have become very much increased in size, so as to materially affect her health. She is very subject to sore throat, attended with severe febrile affections. She is of a dark complexion, black hair and eyes, quite thin, and rather tall of her age.

The tonsils are very large, fleshy, and vascular, and present less of that indented appearance usually observed where there have been frequent inflammations. When the respiration is quiet, the tonsils touch each other. The chest on examination is found to be very much deformed, presenting that alteration, called excavated sternum, in its most exaggerated form; the hollow lining almost large enough to contain a small orange: this deformity has been, for many years, observed by her parents.

The breathing at night is very difficult and noisy; she is subject to attacks of deafness, and at present does not hear unless addressed in a loud voice.

The right tonsil was removed on the 12th, and the patient at once relieved by it; five days afterwards the other tonsil was removed, leaving the throat perfectly

free. On the 25th I saw the patient, and the mother informed me that all the previous bad symptoms were removed—that the child has quite recovered her health. The difficulty of breathing is relieved, and her hearing returned; a cutaneous eruption which had long troubled her has disappeared.

To these cases might be added one or two in which these organs were removed while the patient was labouring under an attack of severe tonsilitis. In one case the symptoms were immediately removed by the operation; in another inflammation had extended to the adjacent parts, and an abscess formed, as is often in this disease. The affection, however, was much shortened in duration, lasting four days, instead of fourteen, as had been usual with this patient, who was liable to attacks every winter. The operation was repeated, and the other tonsil was removed on a subsequent attack, with the same result.

Some time since I communicated to this society the case of a young child from Maine, who was brought to Boston suffering from a disease of the throat. The parents seemed to be quite unconscious of the cause of its troubles. There was great difficulty of breathing and deglutition. The child had a spoon, the bowl of which it placed almost instinctively in its mouth when going to sleep; its health was very miserable. The trouble was entirely explained by the discovery of the enlarged tonsils quite obstructing the throat. Their removal of them was followed by great relief.

The mother informed me that another child had died with the same symptoms a few years previous, the cause of its illness being unknown. They resided in an obscure spot, distant from any competent medical advice.

In these cases of the disease occurring in infancy where deformity of the chest exists, Dupuytren advises that this affection should be treated in the following manner:—The child being placed in the lap of its nurse, the hand is pressed on that part of the sternum or ribs which projects; a strong pressure is then made during inspiration, and removed during the movements of expiration. This repeated for many times daily, and continued for a long period, finally results in the disappearance of the deformity, or in a great improvement of appearance. As has been attempted to show above, however, it will be evident to all that the symptoms arise, certainly in the great number of cases, not from the deformity, but from the obstruction in the throat to the free passage of air.

The instrument\* used in these opera-

\* Invented by Caleb Eddy, Esq., of Boston.

tions, has usually been the guillotine instrument, as described by Dr. Warren in his work on Tumors, being somewhat similar to that of Dr. Physick; it is, however, without the steel movable needle used to fix the tonsil and prevent it from falling into the throat, which appears to be useless, as the blade of the instrument drives the lining membrane of the tonsils into its groove, and thus secures it; and even if this were not the case, the mucus which covers the fauces causes the excised part to adhere to the blade, so that there is no danger of its escaping into the throat.

In very young children, where the passage of the fauces is narrower, a more delicate instrument, invented by Dr. Fahnestock, of Pennsylvania, is, perhaps, preferable\*.

## ROYAL COLLEGE OF SURGEONS IN LONDON.

*To the Editor of the Medical Gazette.*

SIR,

I AM directed by the President to transmit to you the inclosed copy of Regulations, lately established by the Council of this College, relating to professional education of candidates for its diploma, now commencing their professional studies.

I am, sir,

Your most obedient servant,  
EDMUND BELFOUR, Sec.

October 23, 1839.

*Regulations of the Council respecting the professional education of candidates for the diploma.*

1. Candidates will be required, in addition to a Certificate of being not less than twenty-one years of age, to bring proof—

1. Of having been engaged in the acquirement of professional knowledge during a period of not less than four years; six months of which shall have been occupied in the study of Practical Pharmacy, six months by attendance on the practice of physic, and the remainder of the period on the practice of surgery, at a recognised hospital or hospitals in the united kingdom:—three months being allowed for a vacation in each year.
2. Of having studied anatomy and physiology, by attendance on lectures and demonstrations, and by dissections, during three anatomical seasons or sessions†:—and of having attended

at least two courses of lectures on the principles and practice of surgery, delivered in two distinct periods or seasons, each course comprising not less than 70 lectures:—And one course of not fewer than 70 lectures on each of the following subjects, viz. the practice of physic—chemistry—materia medica—and midwifery, with practical instructions;

II. Members and licentiates in surgery of any legally constituted college of surgeons in the united kingdom, and graduates in surgery of any university requiring residence to obtain degrees, will be admitted for examination on producing their diploma, license, or degree, together with proofs of being 21 years of age, and of having been occupied at least four years in the acquirement of professional knowledge.

III. Graduates in medicine of any legally constituted college or university requiring residence to obtain degrees, will be admitted for examination, on adducing, together with their diploma or degree, proof of having completed the anatomical and surgical education required by the foregoing regulations.

IV. Certificates will not be recognised from any hospital unless the surgeons thereto be members of one of the legally constituted colleges of surgeons in the united kingdom; nor from any school of medicine or midwifery, unless the respective teachers be members of some legally constituted college of physicians or surgeons in the united kingdom, nor from any school of anatomy or surgery in England, unless the respective teachers be members of some legally constituted college of physicians or surgeons in the united kingdom, and have undergone a second or special examination on those branches of science, according to the ordinances of this college relating thereto.

V. Certificates will not be received on more than one branch of science from one and the same lecturer; but anatomy and physiology—demonstrations and dissections—will be respectively considered as one branch of science.

N. B. In the certificates of attendance on hospital practice and on lectures, it is required that the dates of commencement and termination may be inserted in words at length.

Blank forms of the required certificates may be obtained on application to the secretary, to whom they must be delivered, properly filled up, ten days before the candidate can be admitted to examination; and all such certificates are retained at the college.

By order of the council,

EDMUND BELFOUR, Sec.

August 20th, 1839.

\* American Journal of Med. Sciences.

† An anatomical season is understood to extend from October to April inclusive, and to comprise at least 140 lectures on anatomy and physiology, occupying not less than one hour each, given on separate days; and at least 100 demonstrations of the like duration, given in a similar manner; exclusive of dissections, of which distinct certificates are required.

## DR. BARON'S PAPER.

*To the Editor of the Medical Gazette.*

SIR,

I TAKE the earliest opportunity of acknowledging the inaccuracy pointed out by Dr. Gregory in your last number. How it escaped the observation of the gentlemen who examined the report before it was submitted to the Section, I cannot tell; and I am still more at a loss to understand how it did not attract my own attention, as I had, on a former occasion, quoted the facts from Mr. Crosse's book, and they accord entirely with those mentioned by Dr. Gregory, (see *Life of Jenner*, Vol. i. p. 282.)

The examination of a great multiplicity of documents, and the hurried and broken manner in which medical men are for the most part constrained to carry on their inquiries, will in some degree explain, if it does not altogether excuse, the mistake that has been committed. Should other errors be detected, I am sure that every member of the Section will be glad to have them pointed out and corrected, as their sole object is to discover and diffuse the truth.—I remain, sir,

Your obedient servant,  
J. BARON.

Cheltenham, October 22d, 1839.

## MARISCHAL COLLEGE.

WE learn that the Crown has instituted a Professorship of Anatomy and one of Surgery in Marischal College and University, and has presented Allen Thompson, M.D., Lecturer on Anatomy in Edinburgh, to the former professorship, and William Pirrie, M.D., formerly Lecturer on Anatomy to King's and Marischal Colleges, to the latter.—*Aberdeen Herald*.

## MEDICAL APPOINTMENT.

DR. FOX has been elected to succeed Dr. Thomas Davies as Physician to the Infirmary for Diseases of the Lungs.

## FRESH VACCINE VIRUS.

DR. CHARLES A. LEE, of New York, informs us that he has lately obtained virus from a cow affected with kine pock. It is very common, he states, for the cows that go on board our New York, Liverpool, and Harre packets, to have this disease; and the cow from which I got it came from one of these packets. The agent informed me that there is hardly a time in the year but that some of the cows are affected with it.—*Amer. Journ. of Med. Sciences*.

LECTURES  
ON THE  
PRINCIPLES AND PRACTICE OF  
SURGERY.

*Delivered at the Westminster Hospital School,*

By BENJAMIN PHILLIPS, F.R.S.

*Introduction.*

GENTLEMEN,—That a competent knowledge of the history of surgery is a very desirable acquisition for a student in medicine, no one I apprehend will deny. That such a history is a fitting introduction to a treatise on surgery, is equally certain; but the extent of a course of surgical lectures is far too limited to justify me in occupying your time with a subject which must yield in importance to many we have to consider. I must therefore content myself with referring you to those sources from which it may be gleaned.

I say gleaned, because, with the exception of a short sketch by Mr. S. Cooper, and one in the *Dictionnaire de Médecine*, by M. Dezcimeris, nothing like a separate history of the science exists. Still you may obtain what is necessary by consulting Cabanis' *Revolutions of Medicine*; Sprengel's *History of Medicine*; a sketch, by Bostock, and another by Gaste.

Between medicine and surgery no line of demarcation can be drawn so as exactly to define the relative province of one or the other;—none which would be useful to the progress of science or the cause of humanity. The early masters, or, as they have been termed, fathers of medicine, were fully sensible of this, and they practised indiscriminately both sciences. The school of Alexandria is the only early exception to this rule. If we consult the

writings of Herodotus, we find that among the Egyptians the practice of medicine was subjected to almost infinite subdivisions: they had as many classes of professors of the healing art as there were organs in the human body subject to disease. But, in 1163, the Council of Tours issued a decree by which that union was ruptured which had been consecrated by the practice of more than fifteen centuries. By that decree, the clergy, who shared with the Jews the exercise of medicine in Christian Europe, were prohibited from performing any bloody operation. At this period a very large majority of the practitioners of the healing art were attached to the church, and though they were not connected with the religious castes by indissoluble bonds, the law of celibacy which was imposed upon them always gave them a right to resume the ecclesiastical state; and their success in the healing art frequently conducted them to the richest benefices and the highest dignities. It was therefore natural that they should conform to the laws of the church, which promised them at the decline of their career honours and fortune. It was probably obedience to the canons of Councils, as much as to a false delicacy and a ridiculous vanity, that induced these doctors to abstain from the practice of surgery. For a long time previously they were in the habit of employing their barbers to perform, under their eye, dressings which did not require the hand of a surgeon. Either in consequence of fortuitous circumstances, or to avoid having recourse to rival practitioners, they gradually employed the same men to bleed, to open abscesses, and other similar operations. Surgeons themselves, who in those days performed only minor operations, contributed to extend this evil by employing these men in the more menial offices

connected with the exercise of their art; and dearly they paid for it. The barbers soon discovered that their new calling was more desirable than shaving beards and dressing hair, and were not long in regarding it as the most important branch of their profession: they laboured hard, and at last, in those days of privileges, they succeeded in obtaining in many European countries a legal sanction. Under the shade of their new constitution, and vulgar credulity, they daily encroached upon the paths of science, undertook the treatment of the gravest diseases, and at last openly styled themselves surgeons.

Although I am not aware of any legislative enactment in our own country of an earlier date than the reign of Henry the Eighth, letters-patent appear to have been granted in the first year of the reign of King Edward the Fourth, granting to the members of the Barbers' Company in London, using the mystery or faculty of surgery, the exclusive right to practise as surgeons within the city of London and the suburbs thereof. The Society of Barbers continued so incorporated until the thirtysecond year of King Henry the Eighth, when the surgeons appear to have become an equally dignified body with the barbers, and were incorporated with them under the name of the Commonalty of Barbers and Surgeons of London, and the barbers were precluded from exercising within the city, and one mile thereof, the practice of surgery, except drawing teeth only, while the surgeons were precluded from exercising the feat or craft of barbering or shaving.

We cannot without interest contrast the position of the science of surgery in the reign of Henry the Eighth, with that which it now occupies. Scarcely elevated above the barber—precluded only by legislative enactment from combining the feat or craft of barbering with the mystery or cunning of surgery—suspected by the legislature of employing sorcery and witchcraft, as well as using medicines—what a picture does this present of a profession which has produced a Pott, a Hunter, and an Abernethy! It was not until the middle of 1745 that the surgeons were separated from the barbers, and incorporated by themselves. It was not until the year 1815 that any restraint was imposed upon the practice of medicine or surgery in other places than London and its neighbourhood. From the hour of this separation by religious prejudices, physicians and surgeons have been struggling for chimerical rights which they can never obtain.

I have pointed out how the separation

was brought about. I will now proceed to show you why it cannot be maintained.

Medicine, in its proper acceptation, is composed of four principal parts—anatomy and physiology: the first informs us of the disposition and structure of organs; the second of their properties and their functions. Hygiene, the art of preserving health, or so using external things and our own faculties as to preserve our organs and prolong life. Pathology, which is the science of diseased man: all the derangements which our organs can experience, either in their relative disposition in their internal structure, should be ranged in its domain; whatever may be the tissue, the organ, the system, or apparatus affected, whatever consequently the seat of the disease, we must define pathology to be the derangement of one or many functions of the economy. And Therapeutics, which is the art of treating diseases: and as the relief or cure of disease is sometimes the effect of regimen, at other times of the administration of medicine, and sometimes results from an operation of the hand, therapeutics must be divided into dietetic, pharmaceutic, and surgical. Surgery is therefore only one branch of therapeutics. We are not, then, justified in regarding the last science as the art of cure: there are diseases which it cannot cure; there are others which it should not cure; and among those which it cures, the honour of the cure frequently belongs to nature. Thus Baglivi commences his *Præceps* with that beautiful homage to the autocracy of nature:—"Medicus naturæ minister et interpres quidquid faciat et ferat si natura non obtemperat naturæ non imperat."

We have sufficiently indicated the place which surgery occupies in medical science;—we have seen that it is really only a therapeutical agent. We may now seek to define what is its real object, and endeavour to place between it and medicine, boundaries which may distinguish, without separating them. We may define surgery to be the mechanical part of therapeutics: "*quod in therapia mechanicum.*" We do not resort to surgery until the insufficiency of dietetical and pharmaceutical means is demonstrated. It is not until all the resources of regimen, diet, and pharmaceutics, have been exhausted, that the assistance of surgery is invoked: it is the last, but the most efficacious. Of this Hippocrates was well assured when he composed Aphorism vi., section 8. "*Quæ medicamenta non sanant, ferrum sanat; quæ ferrum non sanat, ignis sanat, et quæ ignis non sanat insanabilia.*" A plethoric person is me-

naced with apoplexy; a change of regimen and the administration of evacuates are too slow in their action: a surgical operation, bleeding, is necessary: it saves him. The same operation is the only efficacious remedy in acute visceral inflammation: diet and evacuates are not sufficiently prompt: the danger is too urgent. A limb is struck with gangrene by a contusion: it is impossible to employ hygienic means; pharmaceutical means are equally useless: the vital properties of the part are extinguished. Mechanical or surgical means can alone reduce a dislocation. In fact, all the means which surgery employs are mechanical. This division is so well founded in nature, that it may be strictly applied to points where the different parts of therapeutics seem to be confounded. Thus a phlegmon requires for its treatment the successive employment of diet, medicines, and surgery. The latter does not become necessary until after the termination of the disease, to make a way for the pus which fills the abscess which has succeeded to the phlegmon. Diet, diluents, topical applications, direct their action upon the vital properties, and serve to limit inflammatory action; surgical treatment is not necessary until after the abscess is formed. Surgery, therefore, does not constitute a science separate from medicine; it is only a means, the most powerful, it is true, and the most efficacious. In the middle of the eighteenth century, of that age regarded as the age of philosophy, the first surgeon of one of the French kings, Lapeyronie, proposed to a minister of the day to raise a wall of brass between medicine and surgery. The answer of the minister was admirable—"On which side would you place the patient?" Still, up to the present day, the common idea is, that these two parts of the same art are essentially different. We maintain, with Celsus, that the different parts of medicine are not susceptible of a rigorous separation, and that, in the division which religious prejudices effected, that portion of it is best which embraces the largest field:—"Atque ubi se diviserrunt eum laudo qui quamplurimum percipit."—Præfat. lib. vii.

Since, then, surgery is only one of the elements of therapeutics, there can exist no true difference between the physician and the surgeon, which is not to the advantage of the latter. In fact, he possesses one means more than the physician to accomplish the cure of disease; the operation in his hands, is the complement, as it were, to the resources of therapeutics; it supplies by mechanical means, the insufficiency of regimen, aided by medicines. But unfortunately, to administer the suc-

cour of his art, which consists in a manual operation, many indispensable qualities are necessary, which are denied to the greater number; those qualities, as described by Celsus, you all know are contained in the seventh book, commencing with "*Esse autem chirurgus debet adolescens.*" Unquestionably, of the qualities mentioned by Celsus the most desirable is *sang-froid*; it is more rare than address. Dexterity may be acquired by exercise: firmness of mind is a gift of nature. It was refused to Haller, upon whom so much was lavished; he says "*Et si chirurgica cathedra per septem decem annos mihi concredita fuit, et si etiam in cadaveribus difficillimas administrationes chirurgicus frequenter ostendi, non tamen unquam vivum hominem incidere, sustinui nimis ne nocerem veritus.*"—*Bib. Chir.* 1775, vol. 2, 4to.

Still he who is armed with a competent knowledge of anatomy does not hesitate to undertake the most difficult operations, especially if he have a perfect knowledge of the disease. Yet the habit of practising upon the dead body is a material assistance, in those operations which are performed according to prescribed rules. If, however, I may judge from my own experience, in a first operation, the shedding of blood, the cries of the patient, and the novelty of the situation, render it difficult to avoid a species of excitement which I apprehend bears some analogy with that which a soldier experiences in the tumults of a battle and the aspect of the carnage. There can be no question that Heister was right in his dictum, that it is neither study, nor meditation, nor dispute, but practice, which makes the surgeon.

Surgery is not only the art of operating, though this may be the most brilliant part of it; the surgeon should know not only why, where, but how and when it is necessary to operate—should be perfectly aware of what it may be necessary to do before, during, and after the operation; he ought to use every means to render it unnecessary, and should not have recourse to it until every milder means has been exhausted. It is not, then, until the insufficiency of hygienic and pharmaceutical means be fully proved, that recourse should be had to surgical operation. All men, however, cannot perform great operations; this practice, which essentially constitutes the surgeon, supposes the exercise of the art in the hospitals of large towns; it is consequently the province of a comparatively small number of persons. Yet if all men have not the firmness of mind necessary to enable them to employ the knife and the fire upon the living body, for the purpose of obtaining cures which

have resisted other means—if the greater number want the opportunities to acquire it, as well as that dexterity which frequent practice gives—all should know, although they may be unable to execute, when it is necessary to have recourse to it.

It may be objected to my mode of viewing the subject, that to excel in all branches of medicine is very difficult; but then rules are laid down for the greater number, and a small number of exceptions, far from destroying, confirm them. We may also advantageously refer to the example of the ancients. Surgical genius is not incompatible with great knowledge of the other branches of medicine; the greatest masters are a proof of this; and among those whose particular tastes, or other circumstances, have removed them from the practice of operations, many have not only practised, but have taught the science of surgery.

The science and practice of surgery require of him who desires an honourable name, and distinguished professional rank, long sustained and well directed exertion. The ancient languages should be familiar to him, not only to enable him to master the works on medicine and surgery composed in those languages, but to enlarge his mind by meditating on the illustrious works of antiquity. The progress of science, and the great and general diffusion of knowledge, render an acquaintance with modern languages, physics, and natural history, essential elements of a liberal education; and it behoves the medical man—a member of a learned profession—so to cultivate literature and philosophy, as to maintain the position long conceded by public opinion to the professors of medicine. I would therefore strongly urge on the attention of all who hear me, that before attendance on medical lectures begins, considerable progress should be made in the studies I have recommended. If this preliminary knowledge be not acquired early in life, it is highly probable it will not be acquired at all; and if the time usually devoted to attendance on medical lectures be divided between professional and general studies, it is to be feared that, in the majority of cases, neither the professional nor the general knowledge will be mastered. Entering upon the study of medical science with the preparation I have recommended, your progress will be rapid if your devotion be earnest.

Although I do not propose to insist upon the general utility of the study of anatomy, which will be more ably done by my colleagues who have charge of that department, I will shew you, as succinctly as may be, instances in which modern surgeons have greatly profited by their supe-

rior cultivation of this, the only staple foundation of the knowledge of man. If we take the organs of the pelvis—thanks to the labours of Scarpa and others—we can now appreciate with almost mathematical exactness the advantages and inconveniences of the different modes of proceeding which have been adopted for the extraction of vesical calculus. By directing attention more strongly than had previously been done to the middle lobe of the prostate, Sir E. Home explained a frequent cause of retention of urine. By demonstrating that the curvatures of the urethra were less decided than had generally been supposed, Amussat paved the way for the more successful employment of straight instruments in the destruction of stone. Take the diseases of the eye, and the importance of *minute* anatomy is abundantly evident. The vascular texture of the iris induced Travers to suspect that it was the principal seat of those serious inflammations produced by syphilis; its presumed muscularity has served to explain the inefficiency of the simple transverse incision of the iris, imagined by Cheselden; at the same time this muscularity has served as a foundation for other modes of establishing artificial pupil. Is it not to the profound study of the smallest branches of the arterial system, whose resources up to nearly the end of the last century were comparatively unknown, that the present treatment of aneurism is owing? This was the foundation upon which Hunter built: before the discovery of the anastomosing system, who would have dared to tie the external iliac—an operation which, since 1796, has succeeded 50 times in 67 cases? It is anatomy which conducts the hand of the surgeon through parts the lesion of which might be dangerous or mortal. It is by anatomy in the last resort that we judge of methods of operating; it precedes experience, and indicates in what manner our organs may be most safely approached. It is anatomy which, when reverses come, unveils to the surgeon the sources of those reverses, and points to him the modifications to be introduced into an operation, if the reverses have attached to the mode of operating. Relations which anatomy had not at first revealed, serious accidents supervening upon surgical operations have shewn the importance of. Thus, it was not until the operation for strangulated crural hernia had been followed by numerous failures, that Arnaud, Richter, and Scarpa, discovered their source to be in the disposition of the spermatic cord and the epigastric artery with reference to the neck of the sac. These and many others are great and important innovations in surgical

science, attributable to an improved knowledge of the anatomy of the human body; but the importance of anatomy to the surgeon may be exaggerated, and observation and experience have not infrequently contradicted assertions which have been based simply upon the structure of the parts. Thus the luxation of the femur backwards and downwards was regarded by Boyer as an impossibility, but has been many times observed. Many similar examples might be given, but they are unnecessary. We are bound to admit that the greatest discoveries have given rise to the most reprehensible abuses. I hold such an abuse to be the ablation of certain organs whose situation and texture should have afforded them protection. Of this number I class the attempt to remove the thyroid body; more than one patient has died either under the knife of the operator (Gooch, Klein, and others), or soon after; and even in those cases where the extirpation has been completed, such as the cases of Gooch, Hederus, Walther, and others, through how much pain and danger have those cures been accomplished, of a disease ordinarily supportable. In the same class I would place the attempts to extirpate the uterus. Whilst, therefore, I maintain that surgery has derived much of its glory from anatomy, I would urge upon you the necessity of a discreet and cautious application of anatomical knowledge to surgical science.

Those persons are ill informed who think that surgery is a readily acquired science; like medicine, it has its difficulties and uncertainties; as in medicine, success will not always follow skilful surgical practice; like medicine, it derives great assistance from investigations in pathological anatomy. If the knowledge of the anatomy of relation in the healthy state be necessary to enable the surgeon to perform operations upon healthy parts, the knowledge of the change of those relations by disease is not less indispensable to enable him to appreciate the best method of directing his instruments among parts which have contracted other relations. Who will dare to undertake an operation if he do not know with certainty the nature of the disease—its limits—its tendency, if it have any, to reproduction—its connexion, if there be any, with particular internal affections. What suggested to Dupuytren the method of curing artificial anus? Pathological anatomy. The examination of bones fractured by accident in man, or by design in brute animals, produced in the minds of Hunter and Scarpa the conviction that the callus is not simply an osseous piece, concentered by degrees, as was supposed by Haller and

Dethleef. Look at the work of Sir A. Cooper, to learn what pathology has done for dislocations. Take the different varieties of cancer of the testicle, and we find that English surgeons have enabled us to distinguish between medullary and fungous disease; the former requiring castration, the latter only excision, of the fungus.

If by physiology we understand the natural or spontaneous phenomena of the organization, no branch of the art of cure should be more fruitful in discovery, or have a greater tendency to advance to the highest state of perfection the sciences of medicine and surgery. It is to observation, based upon physiology, that we owe the simplification of the method of treating wounds, and the proscription of unguents, plasters, and similar preparations, formerly so liberally used—that we owe union by the first intention, and the various modifications of treatment founded on it; and to this union we owe the science of grafting, at present so beneficially employed in the relief of many infirmities to which humanity is exposed. It is by physiology we explain why intestinal strangulation so seriously compromises life, and why it is so necessary at once to relieve it—whence the danger of aneurism, and how we may avert a fatal termination—whence, in certain cases, the sterility of women, and the impotence of man—how, by the powers of the uterus, the mother brings forth the fruit of her conception—and how, when danger is pressing, surgery may offer succour no less efficacious to the mother than the child.

Experimental physiology has rectified errors regarding the circulation: thus the experiments of Nysten proved peremptorily that a considerable quantity of air may be propelled into the venous system with impunity. It is no longer a single bubble which kills with the rapidity of lightning, as was supposed by Bichat. Thus certain of the risks gratuitously attributed to the opening of veins, and the ingress of air in surgical operations, fatal results can no longer be assigned to the penetration of air, and some other explanation must be found for those frightful syncope which sometimes occur, and terminate alike the disease and the life of the patient. Other similar illustrations might be given, but our time does not admit of our adducing them.

Nothing is more difficult, at the same time nothing is more important in facilitating the acquirement of the science, than a good classification of diseases. But any system of the kind must, in the present state of our knowledge, be artificial and

arbitrary. We do not know enough of nature's laboratory to be acquainted with the laws which govern the development of disease. The ancients and the Arabs described disease *a capite ad calcem*. At the time of the revival of science five divisions of the body constituted the principle of classification; this system, to which Fabricius ab Aquapendente attached the name of Pentateuch, was far from embracing all diseases; in fact, besides tumors, wounds, ulcers, fractures, and luxations, there were many diseases which they were obliged to describe according to the anatomical order previously adopted. The vices of such a system are very obvious; the most fatiguing repetitions were necessary; and these repetitions occasioned the double inconvenience of uselessly prolonging the study, and introducing into it greater confusion. It might be compared to a geographical chart, in which the author did not content himself with inscribing objects a single time, but recorded them as many times as there were points of view from which they could be seen. Besides this, what was there in common between the tumors which they arranged in the same class? What should we say of a naturalist, who, in classing the different objects projecting upon the surface of the globe, should comprehend in the same division trees, mountains, and houses? And yet the bringing into the same class, abscesses, aneurisms, and cancerous tumors, is not a whit less heterogeneous. These diseases are essentially different, and have no other analogy than the tumefaction of the part in which they exist; in their nature they are most opposed, and as to treatment that which would be proper as applied to abscess, would be fatal applied to aneurism. The symptomatic method is not less objectionable. I would almost as soon adopt an alphabetical arrangement; it would not bring together more opposite conditions; in fact, abscess and aneurism would come together in this arrangement. However defective such bases of classification may be, they are very preferable to nosological systems, founded upon the consideration of causes, often unknown, uncertain, and obscure, of many diseases. The ancients seem to have been convinced that diseases could only be classified after a consideration of the affected part; but in describing them after regions of the body, they confounded all the objects of the anatomical methods. They had felt the utility, but they could not obtain the advantages of it, because the science which was to furnish them with a basis was not sufficiently advanced for them to use it. In the present day, when the tissues and organs of the

human body are so well known, and that anatomical analysis is acquiring a precision approaching to the exact sciences, it is impossible to find a better base for classification than the distinction of the different apparatus. With these means, however, it is not probable that we shall ever attain in medicine even to such a degree of precision as has been introduced into botany. The morbid agent is too frequently concealed from our view, its duration is evanescent, its causes are uncertain, its nature is obscure; even pursuing the best method we cannot hope soon to arrive on a level with the other natural sciences. This will probably be a work of ages. After having founded their systems of classification upon a single part of a plant, sometimes on that of a corolla, like Tournefort, sometimes upon the sexual organs, like Linnæus, botanists of the present day prefer to take their characters from the consideration of all the parts of a plant, and class it after a greater number of relations. Medical men, after having successfully employed classifications based upon differences of seat, of cause, of symptom, and of treatment, seek, in the present day, a method more like that of botanists, embracing anatomical, etiological, symptomatic, and therapeutic relations.

I shall first consider those diseases which affect all organic tissues. Inflammation, suppuration, ulceration, mortification, scrofula, cancer, scorbutus, wounds.

*Second*, I shall consider the diseases of each tissue taken separately from the surface to the centre of the body.

*Third*, I shall consider the diseases of the several regions. In this way we shall have GENERAL SURGERY, SURGERY OF THE TISSUES, and the SURGERY OF REGIONS.

It may be asked why I do not begin with wounds. The reason may not be a good one; inflammation is manifested after almost every wound; it is presented in the great majority of local diseases, either as concomitants, cause, symptom, consequence, or as a curative means. All these circumstances would seem to point out the first lecture as the proper place for inflammation. It may be useful also to show the student an example of the intimate union which exists between medicine and surgery; besides, if my reasons appear insufficient, I must shield myself under the cloak of universal usage.

**INFLAMMATION.**—Nature; external characters; essential or anatomical characters; results; changes in the blood; ditto in the secretions; ditto in structure; summary; treatment.

**SUPPURATION.**—Definition; modes in which pus may be formed; its characters, phy-

sical, microscopical, chemical; diffused; circumscribed; constituting *abscess*; the progress of abscess; its treatment; *fistula*; nature; treatment; **HECTIC FEVER.**

**ULCERATION.**—Mode of production; *varieties*; common, indolent, inflammatory, sloughing, phagedenic; *granulation*; cicatrization.

*Specific ulcers will be found under their particular causes.*

**MORTIFICATION.**—Definition; in consequence of the cessation of the circulation, *from a mechanical cause—from debility*; in consequence of the violent operation of mechanical or physical agents—cold, heat, stimuli; in consequence of the deleterious influence of certain poisons; *natural to animals*; consequences of disease in animals and in vegetables; local and general symptoms of each; treatment.

**SCROFULA.**—Nature; causes; treatment.

**CANCER.**—Nature; varieties; anatomical characters; treatment.

**SCORBUTUS.**—Nature; causes; treatment.

**WOUNDS: Mechanical.**—Punctured, incised, contused, lacerated, non-suppurating, suppurating, *GUN-SHOT*; characters; treatment. **Hæmorrhage**; tetanus.

— *Chemical.*—Effects of heat and cold; mineral acids; alkalies and salts; characters; treatment.

— *Poisoned.*—Stings, bites of venomous animals, of rabid animals; dissection wounds; malignant pustule; hospital gangrene; characters; treatment.

**DISEASES OF THE SKIN AND ITS APPENDAGES.**—General principles of classification and treatment; exanthemata, vesiculæ, bullæ, pustulæ, papulæ, squamæ, tubercule, purpura, nævus, onychia, plica, warts, corns.

— **OF THE CELLULAR SYSTEM.**—Phlegmon; furunculus; carbuncle; œdema; tumors, encysted or not.

**INJURIES AND DISEASES OF THE ARTERIAL SYSTEM.**—Wounds; hæmorrhage; treatment; inflammation; ossification; aneurism. History; treatment.

— **VENOUS SYSTEM.**—Wounds; rupture; dilatation; varices; inflammation; nature; causes; treatment.

— **MUSCULAR SYSTEM.**—Wounds; ruptures; contractions; *wry neck*; nature; history; treatment.

— **TENDINOUS SYSTEM.**—Ruptures; wounds; section; ganglia.

— **FIBROUS SYSTEM.**—Periostitis; pericarditis; nodes.

— **OSSEOUS SYSTEM.**—Wounds; fractures; osteitis; caries; necrosis; exostosis; rachitis; fragility; mollities; spina ventosa; osteo-sarcoma; cancer.

— **ARTICULATING SYSTEM: Mechanical Injuries.**—Wounds; contusions; inflam-

mation without and within the capsule; dropsy; loose cartilages; ulceration; white swelling; ankylosis; *luxations* from mechanical violence; spontaneous; **ARTIFICIAL JOINTS.**

— **NERVOUS CENTRES: Head.**—Wounds of scalp; fractures of cranium; concussion; compression; inflammation of meninges; ditto of the cerebral substance; hernia cerebri; fungus of the dura mater.

— *Spine.*—Concussion; compression; luxation; fracture; inflammation of cord; caries; curvature, lateral, and Pott's; spina bifida.

— **NERVES.**—Contusion; inflammation; neuralgia; sciatica; tubercles, or other tumors or cysts, developed in their substance.

— **FACE.**—Wounds; contusions.

— **EYE AND ITS APPENDAGES.**—Injuries and diseases of eyelids of lachrymal apparatus; conjunctivitis, acute, chronic, strumous, gonorrhœal, Egyptian, rheumatic; pterygium; *cornea*; inflammation; opacities; ulcers; staphyloma; iritis; retinitis; glaucoma; amaurosis; cataract; artificial pupil; malignant disease.

— **NOSE AND ITS SINUSES.**—Hypertrophy; lupus; epistaxis; polypus; foreign bodies; *ozena*; *restoration*. **Sinuses**—Inflammation; dropsy; abscess; polyp; malignant tumors; foreign bodies.

— **DIGESTIVE APPARATUS.**—Hare lip; cleft palate; cancer of lip; teeth; salivary glands and their ducts; ranula; tumors and excrescences of gums; wounds; ulcers; cancer of tongue; tonsils; uvula; wounds; abscess; ulcerations of pharynx; foreign bodies; rupture; inflammation and stricture of œsophagus; œsophagotomy.

— **EAR; External Ear.**—Imperforation; inflammation; polypus; foreign bodies. *Middle Ear.*—Inflammation; abscess; caries; puncture of tympanum; perforation of mastoid cells; catheterism of Eustachian tube.

— **THROAT AND RESPIRATORY ORGANS.**—Cut throat; wounds of larynx and trachea; foreign bodies; laryngotomy; tracheotomy; tumors in the air-passages; bronchocele.

— **THORAX.**—Wounds, penetrating or other; ditto implicating heart, great vessels, lungs; hæmorrhage; emphysema; empyema; paracentesis. **MAMMA.**—Inflammation of; abscess; tumors, malignant and other.

— **ABDOMEN.**—Penetrating or other wounds; implicating intestines or other viscera; contusion with or without injury to viscus; abscess of liver or other viscus; hernia of various kinds; artificial anus; invagination.

— **URINARY ORGANS.**—Kidneys; ure-

ters; bladder; prostate; urethra in man, and with the exception of the prostate in women. CALCULUS.

— GENITAL ORGANS IN MAN AND WOMAN.—Syphilis; its history; its varied effects, complications, and consequences.

— RECTUM AND ANUS.—Abscess; fistula; imperforation; prolapsus; hæmorrhoids; excrescences; polypus; fissure; stricture; cancer; foreign bodies.

#### A GENERAL CONSIDERATION OF THE OPERATIONS OF SURGERY.

The extent of a course of surgical lectures does not admit of our entering into discussions upon every occasion where it might be useful, nor to mention the authors of all the observations we may use. We can only engage in discussions on occasions when it is necessary to combat some error, or to express some new view. In the immensity of facts which must be brought together to seek the truth in any point of practice, I have employed only those of whose authenticity no doubt could fairly be entertained. Great care is clearly necessary in such cases, or we may be imposed upon by names or appearances. Men of great reputation, and writers of considerable authority, have said, if much scepticism were introduced into medicine, we should too far reduce the number of fundamental propositions; that the science would be destroyed. We think this a question which affects too nearly the interests of humanity to admit of a hasty decision. Still, if a general inventory demonstrated that we possessed only four incontestable truths, I should not hesitate to publish the results, and I should believe that by so doing I should be rendering essential service to science; in shewing that men had long been satisfied with base coin, which should be discarded, and in demonstrating that our efforts should be directed to substitute truth for error. If the fear of error causes naturalists, astronomers, and others, to regard all *facts* with so much jealousy, how does it happen that that jealousy and that circumspection are not equally necessary to the medical man? I think the medical man's *facts* should be quite as rigorously sifted, and he should not accept them, until they have been so frequently reproduced under the same essential circumstances, as to render the demonstration complete. Before the great revolution which chemistry experienced in the eighteenth century, the science scarcely existed; chemists, it is true, had raised a large mass of scaffolding composed mainly of vain chimeras. They had admitted probabilities where a little

trouble would have given certainties—and how widely they diverged from their proper course! Men of sounder and vaster intellects came; they grasped this edifice, and it crumbled to dust, and disappeared; but the true science was substituted for it, founded upon a solid foundation—well ascertained facts. This example we should steadily regard; we should learn how much the natural impatience of the human mind lays it open to error, with what facility it is perpetuated from age to age; years, and the credit of able men who have admitted them, giving to them a new and more irresistible authority. Medical truths are not easily acquired; the facts we have to study do not present either the simplicity or the uniformity of those in the domain of physics; they are variable and complicated: a small number of circumstances only have a character certain enough to fix the attention of an accurate observer; and much ability, patience, and caution, are necessary to avoid accepting a truth before the demonstration is complete. Long and profoundly impressed with these principles, without which science can never have a solid foundation, I have, as much as may be, made, or endeavoured to make, an inventory of what is best established in the healing art. I have not lightly decided on any question. I have not insisted upon those things which seem insufficiently demonstrated; I have not presented probabilities except as such, and I have left doubtful all which appeared to offer a consideration of the facts by which they are supported. It would be unjust to say that such a course was baneful—that it was an attempt to destroy a science because its foundations were not solid. We do not seek to change the face of the science we cultivate, but we believe it to be the duty of every man who respects himself, to point out errors if he have detected any; and to give to those who are able, opportunities of repairing defects, of filling up the lacunæ which may be pointed out. There are many errors accredited because they have been sanctioned by eminent men: they are extremely difficult to eradicate. To lay violent hands on such things may appear a violation or profanation to those who do not look beyond the surface, and who hold that time consecrates error. It is only by such means that our science can be elevated, and hold its proper place among its fellows.

## CLINICAL LECTURES

ON

## OPHTHALMIA.

BY M. VELPEAU.

*Reported for this Journal, by*

J. HENRY BENNET, B.L. &amp; B.S.

Sorbon.

*Local treatment of acute iritis — Mercurial ointment — Belladonna — Various cecylria — Puncture of the cornea, a dangerous expedient — Chronic iritis — Efficacy of issues — Synechia — Operation for the removal of this — Application of belladonna — Critical examination into and denial of the existence of catarrhal and various other specific forms of ophthalmia.*

THE influence which local treatment exercises over iritis is certainly slight—a fact which the deep-seated situation of the inflamed organ at once explains; I cannot, however, agree with M. Siehel in considering it to be decidedly prejudicial. In many instances I have seen the iritis itself benefited by the use of local remedies, and you are well aware that they are valuable therapeutic agents in the treatment of the inflammation of the cornea and of the conjunctiva which nearly always accompanies inflammation of the iris.

Local remedies may be divided into two classes. The first class comprises those which act directly on the iris; the second those which only act on the membrane through the medium of the circulation. In the first class we find the various mercurial, opiate, and belladonna ointments, the action of which we will now examine.

Although mercurial ointment has enjoyed, and still enjoys great reputation, it has never in my hands proved a valuable remedy. Indeed, I have so often employed it without deriving any benefit whatever from it, that I cannot now place much confidence in its efficacy. You ought early to become familiarized with the idea that a multitude of remedies employed by every practitioner, exercises, in reality, little or no influence over the disease against which they are directed; nor is it difficult to account for the apparent contradiction. In iritis, for instance, after some substance or other, say mercurial ointment, has been applied to the temples during several days, the inflammation disappears. It is at once inferred that it has given way to the application of the ointment. But in all probability some of the general measures which we have already detailed, such as general or local bleeding, have been simultaneously employed, and it then becomes difficult to

decide whether the iritis has been cured by the mercurial ointment, or by the other remedies to which the medical practitioner has had recourse. We must also bear in mind the length of time the disease has already existed, when we wish to ascertain the value of a remedial agent which we have employed; because iritis, in this respect similar to all other inflammatory affections, does not last for ever, and may disappear after a certain lapse of time, although no treatment whatever has been directed against it.

When iritis is accompanied by severe pain, and it is considered advisable to guard against the contraction of the pupil, ointments containing opium and belladonna are indicated, the proportions for these ointments being one drachm of opium or belladonna to an ounce of hog's lard. Belladonna having a peculiar action on the pupil, has been much used in the treatment of iritis; we will therefore, devote a few moments to the examination of its value as a therapeutic agent in this disease. In the first stage of the malady, while the inflammation is still acute, belladonna should not be employed, as, instead of diminishing, it increases the inflammation. The action it then exercises over the iris may be compared to that of a remedy which would oblige an inflamed muscle to contract, in order to cure the inflammation. But when the inflammation has in a great measure subsided, and we have to fear, as sequela, permanent adhesions between the radiated fibres of the iris, or between the iris and the adjacent organs, belladonna is extremely useful, and will often, if judiciously employed, cause the destruction of any slight adhesions which may have formed. Among the various preparations of belladonna which are employed, there are one or two which, in my opinion, ought never to be used unless the inflammation has entirely disappeared. I cannot, for instance, understand how some practitioners can recommend the concentrated solution of belladonna to be instilled into the eye when the resolution is not complete. This solution is, in reality, an extremely irritating preparation, as is plainly seen if a few drops are introduced between the eyelids of a person whose eye is not inflamed:—the eye immediately becoming red and painful. It is not, moreover, necessary to employ it when the inflammation has not entirely subsided, as the iris may be easily acted upon either by frictions with belladonna ointment, or by giving some preparations of belladonna internally. The principal object we have in view in employing belladonna is to produce alternate contraction and dilatation of the iris, in order thereby to destroy the

adhesions that may exist. To accomplish this, certain precautions are necessary. Were the belladonna given every day, its action being slow and gradual, the adhesions would not be ruptured, but merely elongated. We are, therefore, much more likely to succeed if we give the belladonna every two or three days, by starts as it were, so as to cause the pupil to dilate suddenly.

Among the remedial agents which constitute the second class of local remedies, there are very few of any value. The various collyria of lead, iron, &c. are of little or no use, unless there be at the same time conjunctivitis or superficial keratitis. When, indeed, we consider that the surface on which they are applied is separated from the iris by the entire thickness of the cornea and by the aqueous humour, we cannot be surprised that they should exercise but little influence over the disease. As, however, collyria containing laudanum and belladonna sometimes appear beneficial, they may occasionally be employed. When they are resorted to, the eyelids should be bathed several times a day with the collyria, and if the inflammatory stage is passed, a few drops may be instilled into the eye.

When the various agents which I have enumerated do not appear to arrest the progress of the inflammation, there are other local remedies which may be tried, as they have been strongly recommended by some authors. I might name, for instance, the distilled water of the lauro-cerasus, in which cyanuret of mercury has been dissolved. This collyrium has been much used by M. Carron du Villards; but on perusing what he has said on the subject, I do not find that there is any reason to suppose its efficacy to be greater than that of the laudanum or belladonna collyrium. I do not mean to say that the remedy is a bad one, but that its efficacy has not yet been satisfactorily demonstrated.

Before I conclude these remarks on the treatment of acute iritis, I must say a few words respecting a much more energetic remedy than those we have just examined; I allude to puncture of the cornea. Many of you will probably be surprised to hear that such a measure should ever have been proposed against inflammation of the iris, yet not only has it been proposed, but also put into execution. Mr. Wardrop is, I believe, the inventor of this plan of treatment; but since he introduced it into practice, it must have been frequently resorted to, as M. Weller speaks of the puncture of the cornea as of an operation generally adopted in acute iritis by practitioners. Mr. McGregor has practised the operation at least five-and-twenty times.

M. Carron du Villards has often performed it; and an Italian surgeon says that he has punctured the cornea fifteen times on the same patient. The puncture of the cornea having therefore been so frequently resorted to in the treatment of acute iritis, I cannot pass it over in silence, especially as it is a measure which must be either decidedly beneficial or extremely dangerous.

Those who advise the cornea to be punctured in iritis, contend that the puncture evacuating the fluids which distend the eye, alleviates the acute pain felt by the patient, and that when the membranes of the eye are no longer distended, the inflammation is soon resolved. But I have not yet met with facts calculated to prove that such is really the case, and reasoning alone is not sufficient to establish the efficacy of a remedy in the treatment of disease. I have several times punctured the cornea in cases of iritis which presented some special indication, such as accumulation of pus in the anterior chamber, and in every instance the malady has been aggravated. The authors who have extolled this plan of treatment do not say under what circumstances they think it proper to resort to it, but merely state that it is a valuable remedy in iritis. But this is not sufficient: when a peculiar method of treatment is recommended, the precise indication for its use ought to be distinctly laid down. Even from the statements of those who have spoken the most highly of the operation, it would appear that it is not always unattended with danger, as we find that both Mr. Wardrop and Mr. McGregor have seen it followed by the disorganization of the cornea. In my opinion the puncture of the cornea in acute iritis is not a remedy, but a dangerous operation, much more to be dreaded than the disease against which it is directed.

Such are the principal remedial measures to which we can have recourse in the treatment of acute iritis. When they are judiciously and energetically employed from the very commencement of the disease, it generally yields in from six to twelve days. But when the iritis is accompanied by some other deep-seated lesion, such as retinitis, choroiditis, or disease of the vitreous humour, the result of the best directed treatment is far from being favourable.

#### *Chronic Iritis.*

Chronic iritis, considered as a primitive disease, has hitherto been but little studied, nor can we be surprised that this should be the case when we remember that most of the symptoms which characterize the acute form of the disease are absent, and that

consequently its existence must often pass unperceived. If, however, I may be guided by my own experience, I should be inclined to think that chronic iritis is, in reality, by no means an uncommon malady, and that several of those shades of amaurosis which are described under the name of *imperfect* amaurosis may be referred to this affection.

As one of the modes of termination of acute inflammation of the iris, chronic iritis has been frequently observed, and the peculiar characters which it then presents are so manifest that it may be easily recognised. When one eye only is affected, the colour of the iris of the inflamed eye is not the same as that of the one which remains healthy. If the eye is exposed to the light it becomes moist and watery. A sensation of uneasiness scarcely amounting to pain is felt in the orbit, and the sight is more or less disordered. On the anterior surface of the iris spots of various colours may be perceived. The pupil is more or less contracted, and appears to have partly lost its usual mobility; indeed sometimes it remains perfectly immovable, assuming every imaginable shape. Sometimes also adhesion takes place between the pupillary circumference of the iris and the anterior surface of the crystalline lens. The transparency of the humours of the eye is often more or less impaired. The presence of these symptoms can scarcely leave any doubt in our minds as to the existence of chronic iritis, especially if they exist as a consequence of acute inflammation.

The prognosis of chronic iritis is generally unfavourable, the functions of the eye being seldom entirely restored even in the most successful cases.

The remedial agents likely to prove beneficial in the treatment of this affection are the same as those which are employed in the acute form of the disease, modified, however, in such a manner as to suit the chronic state of the inflammation. Thus purgatives and external revulsives are more especially indicated, whilst blood-letting, both general and local, should only be resorted to occasionally, and that with moderation. Issues are often advantageous, but I do not place them at the nape of the neck—the region generally chosen—as the sub-occipital fossa is better adapted for the application of such a remedy, from the quantity of cellulo-filamentous tissue which it contains. By judiciously combining these measures we sometimes may succeed in subduing chronic iritis, but in the majority of cases the most wisely ordained treatment fails to effect a cure.

Synechia, both anterior and posterior, is a frequent symptom in chronic iritis. The remedies which have been recommended

against this form of adhesion of the iris may be divided into two classes, the surgical and the pharmaceutical. Some practitioners have proposed to destroy the adhesions by means of a needle introduced into the posterior chamber, through the sclerotic in posterior synechia, and into the anterior chamber through the cornea in anterior synechia. The operation is by no means difficult to perform, it is true, but it exposes the healthy parts of the iris to be lacerated or separated from their attachments, and may give rise to serious inflammation of the other membranes of the eye. We must also bear in mind that even when the adhesions have been destroyed, they may be reproduced the following day. Prudence, therefore, forbids our adopting so uncertain a plan of treatment, especially as less dangerous measures will sometimes suffice. Thus, the administration of belladonna may, by causing the pupil to dilate, occasion the rupture of the adhesions. But as I expatiated at some length on the efficacy of belladonna given in cases of synechia, when I spoke of the treatment of acute iritis, I shall not say any thing further on the subject. You must not, however, forget that when these remedies are employed, the treatment must be conducted in such a manner as to cause abrupt and not gradual dilatation of the pupil. The following is the plan I generally adopt:—I dilute a few grains of the extract of belladonna in a tea-spoonful of water, and instil two or three drops into the eye night and morning. I then allow it to rest for two or three days, until the pupil has returned to its natural state, when I again instil the solution of belladonna. I must once more remind you that I never use the solution unless the eye is perfectly free from inflammation. If a certain degree of inflammation still exists, I have recourse to frictions round the orbits with belladonna ointment, or I give it internally. By basing my practice on these principles I have sometimes successfully treated cases of chronic iritis accompanied by synechia.

#### *Specific Ophthalmia.*

I have hitherto, in the course of these lectures, avoided employing the epithets which ophthalmologists generally join to the real name of the various inflammatory affections of the eye, as I wished first to make known to you my own opinions respecting this class of diseases. Now, however, that we understand each other—now that I have fully explained the peculiar views which I entertain—we are prepared to discuss the question of the existence or non-existence of specific ophthalmia.

Before I enter into the examination

of this interesting question, I think it is necessary to state, once for all, that in what I am about to say I have not the slightest intention to be personal. I know too well that science has nothing to gain from personal quarrels to wish to engage in them. When, therefore, I mention names, which I shall occasionally be obliged to do, I wish it to be understood that I have merely in view the opinions professed by those to whom I allude. I consider it my duty to attack doctrines which I look upon as erroneous, even should I by so doing incur the displeasure of persons who may be rather too susceptible. Such, indeed, is the conduct which all true friends to the advancement of science ought to follow.

It is of much greater importance than is generally believed to determine whether the inflammatory affections of the eye are or are not of a specific nature. Ophthalmologists of the German school recognize a great number of specific forms of inflammation, the existence of which resting, in my opinion, on theoretical ideas, and not on an accurate and attentive study of nature. I feel myself called upon to do all in my power to prove the falsity of their views; the more so as the elimination of so extensive a class of diseases would evidently tend much to simplify ophthalmology. I do not for a moment doubt that the state of the constitution, or a special affection, may exercise more or less influence over diseases of the eye, for this is a fact which is proved in the most satisfactory manner by daily experience; why, indeed, should the eye be shielded from such influence more than any other organ? I merely assert, convinced as I am by an immense number of facts of the truth of my opinions, that it is absolutely false to say that diseases of the eye assume peculiar anatomical characters because the patient is under the influence of a peculiar general affection, and that we may judge of the constitution of a person labouring under ophthalmia from the peculiar symptoms which that ophthalmia presents. Were this doctrine the expression of facts, and capable of demonstration, or in other words, were not the different specific forms of ophthalmia which have been denominated *catarrhal*, *rheumatic*, *scrofulous*, *venous*, &c. mere creations of the imagination of those who describe them, we should necessarily meet with symptoms which would distinguish them from the simple inflammatory affections of the eye. But a conscientious and attentive examination of nature will shew us that such is not in reality the case; indeed, I have frequently, as most of you must acknowledge, given, at the bedside of the patient, the most irre-

fragable evidence of the non-existence of these peculiar symptoms. I therefore feel authorised to give it as my decided opinion that the various specific forms of ophthalmia, about which so much has been said by the German school, and which are so strenuously defended by those who endeavour to propagate the ideas of Beer among us, do not exist, and ought not consequently to be admitted among the inflammatory diseases by which the eye may be attacked. I must, however, except from this general condemnation syphilitic ophthalmia, a class of diseases which may certainly be looked upon as specific. In order to convince you that I view in a proper light the question that is before us, we will attentively examine the symptoms which are attributed to each of these supposed specific affections.

It is scarcely necessary in the present state of science to allude to those forms of ophthalmia to which the epithets of *variculous*, *dartrous*, *hemorrhoidal*, *menstrual*, *abdominal*, &c. have been given. You must all perceive how absurd, how ridiculous even, it would be to recognize them. Were we to do so we should also be obliged to recognize cardiac, intestinal, meningeal ophthalmia, indeed as many forms of inflammation of the eye as there are diseases. I intend, therefore, merely to speak of those specific affections on which the greatest stress is laid by my opponents, viz. *catarrhal*, *arthritic*, *rheumatic*, *scrofulous*, and *syphilitical* ophthalmia. That we may proceed with order in this discussion, we will first carefully examine the descriptions which authors give of these affections, and then, by establishing a parallel between the symptoms, which are attributed to them, and those which the simple ophthalmia offer, we shall easily discover on which side lies the truth. At the same time we must remember that for a morbid affection of a tissue to be separated from all other affections which may occur in that tissue, for it to be considered a special disease, something peculiar must necessarily be found in its symptoms, its progress, its treatment; in a word, it must have, as it were, a separate existence. Otherwise pathology would be an inextricable labyrinth.

M. Sichel being with us the representative of the doctrines which I now oppose, it is in his own work that I shall take the description of the symptoms which are supposed to characterize specific ophthalmia. This interesting and important question deserves much greater development than I shall now be able to give to it; yet, however brief I may be, I feel certain that what I am about to say will prove sufficient to convince those who lis-

ten to me without any feeling of prejudice, especially if they have followed my visits in the wards, and examined along with me the numerous cases we have received and treated this year.

#### *Catarrhal Ophthalmia.*

The seat of this affection is said to be the mucous membrane of the eye—the conjunctiva. The following are the symptoms by which it is supposed to be characterized:—At first the patient complains of slight itching of the eyes, especially of the inner canthus; the eyelids feel rather stiff, and a little mucus collects in the morning at the inner angle of the eye, and sometimes on the free edges of the palpebræ. At the same time the palpebral conjunctiva begins to present the catarrhal form of vascularization, that is, it appears of a rosy hue, and the vessels which it contains form parallel streaks which pass from the free to the attached margin of the eyelids, and lose themselves in that portion of the conjunctiva which covers the sclerótica. Before we go any further, I must ask every attentive and impartial observer if he can discover in these symptoms any thing more than the first stage of mucous or glandular blepharitis; and if, on the other hand, the symptoms of the latter disease are modified when the patient is under the influence of a catarrhal affection? But, to continue. The vascular streaks, which I have just mentioned soon become more numerous; they are sometimes parallel, sometimes interlaced so as to form an irregular network. The entire palpebral conjunctiva becomes of a yellowish vermilion red colour, and the vascularization, extending to the ocular conjunctiva, assumes a peculiar aspect “pathognomonic of the catarrhal affection.” The injected vessels are of a pale red colour; they are nearly parallel to one another, and, following a slightly tortuous direction as they pass on from the circumference of the conjunctiva towards the cornea, become gradually smaller until they terminate at the distance of a line or two from that membrane. The conjunctival redness is, therefore, always separated from the cornea by a white zone, which is formed by the portion of the mucous membrane that has remained healthy. There is neither photophobia nor epiphora. The secretion of mucus becoming gradually more abundant, it concretes during sleep on the free margin of the eyelids, and at the inner canthus, so as to form crusts, which the patients easily rub off in the morning. In the majority of cases the palpebral conjunctiva is covered with granulations of variable size. The pain which the patients feel is superficial, and is compared by them to that sensation that

fine sand would produce were it interposed between the palpebræ and the eye. This symptom is generally more intense towards evening than at any other time, especially if the patient attempts to work by artificial light.

In what authors call the third stage of the disease the injected conjunctival vessels are more numerous, of a larger size, and advance as far as the circumference of the cornea; then it is that we meet with all the varieties of chemosis.

Such are the principal symptoms which are attributed to “catarrhal ophthalmia.” If you will take the trouble to compare them with those which I described when speaking of the various forms of blepharitis and conjunctivitis, you will at once see that the morbid phenomena are the same, and that the existence of these symptoms may be accounted for in the most satisfactory manner without its being necessary to have recourse to the supposition of a special affection. If any of you still entertain doubts respecting the identity of these symptoms, I would advise them to examine, with M. Sichel’s book in their hands, several cases of blepharitis and conjunctivitis that we have now in our wards. They will find that whether the patient be labouring under a catarrhal affection or not, the same group of symptoms is present, and that the only modifications which they offer are those which are caused by the variable intensity of the inflammation.

With regard to the treatment of catarrhal ophthalmia, if you will compare the remedies which are recommended against it with those which you have seen me employ in the different forms of blepharitis and conjunctivitis, you will find that there is but little difference. Experience has, however, shewn me that these opinions respecting the specific nature of a disease which is purely inflammatory, tend, to a certain extent, to give a wrong direction to the treatment. Those, for instance, who follow the doctrines of the German school, employ, against the symptoms which I have just enumerated, general agents, such as blood-letting, external revulsions, &c., although such measures are not often indicated. The most efficacious plan of treatment in these affections is the application of topical astringents on the inflamed surface. I do not, however, mean to say that blood-letting, both general and local, should be entirely laid aside; I am, on the contrary, fully aware that it is often extremely useful, and sometimes even necessary.

To conclude, as the form of ophthalmia to which the name of catarrhal has been given, offers the same symptoms, follows the same course, and requires the same

treatment as the various forms of blepharitis and of conjunctivitis which we examined some time ago, I cannot see why it should be recognised as a separate disease. Ophthalmology is certainly a sufficiently complicated branch of pathology, without our endeavouring to render it still more so by describing imaginary diseases, for such in my opinion is catarrhal ophthalmia.

## ON SYPHILIS.

By HERBERT MAYO, F.R.S.

Senior Surgeon to Middlesex Hospital.

[Continued from page 156.]

[For the London Medical Gazette.]

*Forms of primary syphilitic disease in which mercury is prejudicial or useless—Varieties and treatment of ulcerative phagedæna—Varieties and treatment of sloughing phagedæna—Subject of chancre commenced—Comparison of chancre with common ulcers.*

### II. PHAGEDÆNA.

THE diseases comprehended under the second head of primary local affections, that are liable to be followed by constitutional lues in one or other of its forms, are ulcerative and sloughing phagedæna. They are distinguished by salient differences from other venereal sores; in appearance they are unlike them, and they are generally made worse by mercury. In these facts there is enough to give plausibility to the hypothesis of Dr. Adams, that phagedæna and chancre are produced by different morbid poisons. One is, however, justified in withholding his assent to this opinion, and in waiting for further evidence, by what is known of the influence of the condition of the system in imparting to common ulcers of other parts a spreading and sloughing character. It is through a careful review of all the phenomena presented by both diseases that the true solution of the question can alone be obtained. The inclination of my own opinion, determined by facts which have afterwards to be mentioned, I have already expressed. I believe venereal phagedænic sores to arise from the common poison of syphilis infecting persons of a certain peculiarity of habit, combined or not with a local predisposition to that form of sore.

Ulcerative and sloughing phagedæna (setting aside the milder cases of the former) agree in this, that they have a tendency to produce rapid and extensive destruction of parts. Each, however, acts by its own process, that, namely, from which its special name is taken. Nevertheless, the worst cases of ulcerative phagedæna are commonly attended with partial sloughing; and cases that begin with sloughing occasionally progress by ulceration.

1. *Ulcerative phagedæna* commonly attacks the glans, beginning with inflammatory tumefaction and excoriation of some part of its surface. The ulcer soon assumes the following definite character, which is the same whether it eat deep or superficially—whether it is excavated or level. The surface is soft and yellow, with a few minute points of vascular texture, or of clotted blood, pushing through it. The edge is essentially irregular. The surface of the adjoining skin is of a more or less bright red, up to the border of the ulcer, so that the colour of the latter and of the integument are in strong contrast. The parts around the ulcer are tumefied, but soft. The distance to which the inflammatory swelling and redness extend is variable; sometimes it is limited to the integument immediately bordering the ulcer; sometimes it involves the entire penis.

In the mildest cases, and in the more serious as the disease becomes mitigated, the character given above is often manifested on one side only of the ulcer, and there most strongly at the edge. The other half of the ulcer and edge may have already granulated, and the latter even may be cicatrizing.

An essential character of this disease is its capriciousness. After improving, or being suspended, or even after cicatrization, the ulcerative process will often recommence. The following are accidental features in it:—Sometimes the ulcer opens a small artery, and considerable hæmorrhage ensues; this, as it will be presently shewn, may be salutary. If it threaten to be excessive, or if the patient is weak, and unable to bear the loss of blood, the hæmorrhage can be stopped by cauterizing the bleeding point.

When the ulcer invades both the glans and prepuce, it destroys the former more quickly than the latter. But

it is liable to spread with yet more rapidity in the cellular membrane, between the integument and penis. Mr. Babington, in his valuable notes to Mr. Palmer's edition of Hunter's works, has very faithfully described this incident in the disease. "The ulcer burrows between the body and the skin of the penis, dissecting in its course the corpora cavernosa from the integuments, and creeping upwards from these parts often as far as the os pubis. Under these circumstances the bottom of the sore cannot be fully exposed, and the part which is within view is generally clean, and sometimes slowly healing; while the portion which is concealed is foul and yellow, and secretes larger quantities of a thin brownish discharge. This spreading edge is attended by the usual tumefaction, which may be felt externally as a hard ring encircling the body of the penis, marking the distance to which the sore has extended, and in the progress of the complaint extending nearer and nearer to the root of the penis. As long as this thickened edge is to be felt, so long the sore is spreading. If the bottom of the sore cleans and tends to heal, the improvement may be known by the subsidence of the thickening, as immediately and as certainly as if the whole of the surface were exposed to view."

When the ulcer happens to be thus spreading along the surface of the corpus spongiosum, it is liable to eat through its substance, making an opening into the urethra, which it is afterwards extremely difficult, if not impossible, to close.

In cases where the disease coexists with phimosis, it is masked by the latter, or the case is identified generically only as one of inflammatory phimosis, which may depend upon either of several causes. If, however, on examining the glans through the inflamed skin, there are one or more parts tender and sore on pressure, it may be presumed that the cause is some form of ulceration. Now if the inflammatory tumefaction is inconsiderable, and the soreness trivial and limited in extent, it is necessary only to enjoin rest, with cooling medicine and abstinence, trusting to these means, with frequent syringing with warm milk and water, and cold or tepid bathing to the part, so to reduce the tumefaction that the foreskin may be drawn back, and the sore disclosed. If, on the other hand, the pre-

puce is greatly swollen and red, and there is much inward soreness, and much thin sanious discharge from beneath the prepuce, the case admits of no delay, and the prepuce should be freely divided, either at the upper part, or laterally if the soreness is to one side. In such cases the division of the prepuce is salutary in several ways; and without it the part will slough.

Practically, ulcerative phagedæna may be said to be of two kinds, the virulent and the benign.

The virulent kind, again, occurs with either of two opposite characters. In a person of a vigorous constitution it is likely to be attended with inflammatory swelling of the part, heat of skin, white tongue, frequent and hard pulse.

In a person of broken constitution there may be equally or more rapidly destructive ulceration, with little attendant inflammation, the pulse being frequent and feeble, the countenance anxious, the bearing of the patient nervous and agitated.

It is obvious that the same method of treatment is not applicable to the two.

In the first case venesection to sixteen or twenty ounces, aperient medicine, abstinence, and remaining in the horizontal posture, are the appropriate general remedies. The best local remedies are those that are most soothing; either lint applied kept moist with a solution of opium in water, or a saturnine and opiate lotion, or a bread poultice. These means being used; in twenty-four hours the ulcerative process will often have stopped, and an approach to a healthier character have commenced. Sometimes it is necessary to repeat the bleeding on the next day, or that following. In cases where the disease is discovered on slitting up the prepuce for phimosis, sufficient blood often flows from the vessels of the divided foreskin. If when the inflammatory or plethoric state of the habit has been thus removed, and the patient is cool in body, the pulse tranquillized, the local inflammation lessened, the phagedæna continue, the practice to be pursued is still alternative, depending on the exact condition of the ulcer; if this is still spreading destructively, its surface is to be destroyed by the application of nitric acid. A single application is commonly sufficient. The other method consists in the application of different stimulants. These, which will be named in treating of benign phagedæna, are to be resorted

to if the disease becomes of that character, indolent, and indestructive.

In virulent ulcerative phagedæna in an asthenic habit, bark and wine, with opium at night, are the appropriate general means; the local resource is the application of nitric acid.

The milder form of ulcerative phagedæna is particularly intractable; but its ravages are inconsiderable, the spread of the ulcer being slow, sometimes burrowing, but for the most part superficial. In some cases the ulcer may be seen occupying part of the glans and the adjoining part of the prepuce; the glans and prepuce being red and swollen, the ulcer at one part advancing, at another granulating and cicatrizing, appearing deeper than it is from the surrounding tumefaction. Sometimes it spreads over one half of the glans alone, as a shallow serpiginous ulcer, which one is only justified in associating with the graver forms of phagedæna above described, by its corresponding exactly in appearance (although on an humble scale) with them, by its improving under the same remedies, and generally being worse for mercury, and by the existence of every intervening gradation.

For the treatment of the milder forms of phagedænic ulcer, there are to be recommended, as general means, good air, nourishing diet, with wine or porter, (the system being in good order and the body cool,) and, in addition, bark with nitric acid, or small doses of the iodide of potassium in decoction of sarsaparilla. Locally, nitric acid is again the most efficient application; but it is useless re-applying this painful remedy, when the character of the ulcer returns as often as it is destroyed. Then stimulants are to be employed, the best of which is the Peruvian balsam; and, next, a solution of nitrate of silver. But every remedy of these classes commonly has to be tried in succession, or alternately with lint and simple ointment; the mere change of application seems beneficial.

I have said nothing of the period which intervenes between exposure to infection and the appearance of this disease, as less is known upon this point in reference to phagedæna than to chancre, and the intervals observed by both are probably the same. I likewise postpone the subject of bubo till the same opportunity, the complaint being a rarer attendant on phagedænic ulceration than on chancre.

2. *Sloughing phagedæna*.—Sloughing phagedæna, when produced by the irritation of the venereal poison, does not differ in any respect from phagedænic sloughing produced by other causes. In inquiring into the nature and treatment of the disease, we may, therefore, lose sight of syphilis, and look only to the general theory of mortification. Mortification is the death of a portion of a living body through the cessation of the circulation in it, and is so distinguished from the death of a part caused by chemical destruction of its organization. But mortification may be either determinate, as when a tumor mortifies upon the application of a ligature; or it may be progressive, when terms the gangrene, sphacelus, sloughing, are used to denote it. There are further differences to be followed out under these heads. Progressive mortification may suddenly invade a large part, the extinction of life in which is gradual, and marked by the gradual alteration of sensibility, warmth, colour,—which form of progressive mortification is expressed by the terms gangrene and sphacelus. Or the part invaded may be of small extent, when the term sloughing is commonly used. And, finally, the mortification may spread by superficies alone, layer after layer of inconsiderable thickness successively mortifying. The term phagedænic sloughing particularly expresses the last shade of difference.

Progressive mortification, again, may depend (omitting mention of others) upon either of two causes: it may be produced by a high degree of inflammation, especially when that inflammation supervenes upon parts previously irritated; secondly, however originally excited, it may be maintained, independently of any other cause, by the contact of the part last mortified with the living and healthy part with which it is in continuity.

Sloughing phagedæna exemplifies both of these forms, of which the first constitutes the least serious case. It supposes some sore existing, a chancre or other ulcer, and an inflammatory habit,—inflammation superinduced upon the sores, and the sores sloughing. This case has to be treated like the inflammatory kind of virulent phagedænic ulcer. Blood is to be taken freely, soothing remedies locally applied, and a strictly antiphlogistic regimen pursued. The case already given from Dr. Fergusson's paper, at page 154

of the former communication, sufficiently shews the advantage of this practice in inflammatory sloughing phagedæna, the consequences of neglecting which are exemplified in the following case narrated by Mr. Rose:—T. Clarke, aged 21, of a full habit of body, was admitted into the Coldstream Hospital with six or eight deep irritable sores on his internal prepuce: the surface of these was covered with a dark-coloured slough; they had thickened and highly-inflamed margins, and discharged a very acrid ichor. He complained of much headache and thirst; had a quick pulse, and other febrile symptoms. The sores had been present three days, and were perceived a week after a suspicious connexion: the glands in each groin were enlarged. He was ordered a brisk dose of jalap and cream of tartar, six grains of antimonial powder, and a small dose of Epsom salts every four hours. A cold cataplasm was applied to the part. On the following days the febrile symptoms were much increased. He had restless nights; frequent cold chills; much headache; and a constant, irritable cough. His tongue was covered with a white fur; his pulse was quick, and not easily compressed; and his skin hot and dry. He had much pain in the sores, which were rapidly extending and running into one another; a dark coloured inflammation surrounded them, which terminated immediately in gangrene. [*At this period, looking back at the history of the case, it is evident he should have been freely bled*] He had been freely purged: the cold lotion was laid aside, and the decoction of poppies used as a fomentation. On the third day the sloughing had extended, and a considerable portion of the corona glandis was destroyed: a hæmorrhage took place from it this morning, by which he lost a pint of blood; the artery was tied. Equal parts of balsam of sulphur and oil of turpentine were applied to the sore, and the cold lotion was again had recourse to. The following day the sloughs had no disposition to separate; and on the body of the glans, anterior to the margin of the sore, several dark-coloured spots had shewn themselves. He had violent burning pain in the glans; his face was flushed; his tongue covered with a brown fur; and his pulse 102. The day after he had two returns of hæmorrhage, but not to a great ex-

tent; he was somewhat less feverish, but weaker. The prepuce was slit open, the sore dressed with compound tincture of benzoin, and a fermenting poultice applied over it. He was ordered beef-tea, ammonia, and Dover's powder, at night. The next twenty-four hours the burning pain was relieved, and nothing recurred to interfere with his recovery.

In the second form of sloughing phagedæna, the inflammation which may have helped to convert a sore of ordinary character into gangrene, plays no further part: there is but the sloughy surface, either black and dry, a crust of superficial mortification, or a moist ashen layer of dead tissue, which keeps separating in soft flocculi and putrid sheds, the skin shewing a narrow livid line of gangrene, which keeps its pace with the separation of the slough. The following cases, by Mr. Lawrence, exemplify some of the features of the disease:—

“Louisa Gardner, aged 18, for the last three weeks had been in the streets, drinking and living in continual indiscriminate prostitution. She had been diseased for a fortnight, at first slightly, but more seriously for the last few days. During the latter period pimples had arisen on the labium, had become red and painful, and then spread into a large sore, which had increased rapidly, with some pain, entirely depriving her of rest. At the time of admission, the external organs generally were red, swelled, excoriated, and superficially ulcerated; and there was copious discharge from the vagina. On the left labium and the neighbouring part of the mons veneris, where the parts were swelled but not reddened, there was a sloughing phagedænic sore, three inches long by one in breadth, which had attained that size in the last three or four days. The surface, which was excavated and dis-organized, reddish, greyish, blackish, and bloody at various points, and bounded by a sharp, ragged edge, afforded a copious, ichorous, and offensive discharge. Excepting that the severe pain had impaired the appetite and rest, the general health was undisturbed. The appearance and expression of the countenance were those of a healthy young person.”

“John Reed, aged 32, a sea-faring man, who had been much in hot climates, and suffered considerably from intemperance and illness, had lately returned

to England, and been more intemperate than usual. Three weeks previously he contracted venereal disease: sores appeared on the prepuce, and excoriation was observed on the scrotum and inside of the thigh. The latter had increased in extent for a week, when a portion near the centre began to look black, and to be extremely painful. He was brought to the hospital in the night (the third after the commencement of the phagedæna) in a state of great agitation and alarm, with involuntary tremulous movement of the extremities: 40 minims of laudanum were administered, but did not procure sleep, and he endeavoured to leave the ward under apprehensions of what might be done for his complaints. There were four sores at the base of the prepuce—a larger, with an indurated base, and three smaller, all in a favourable state. The outer side of the scrotum, and the corresponding surface of the thigh, were bright red. In the middle of the fold, between these parts, there was an ulcerated opening, as large as a crown-piece, three-quarters of an inch in depth, with an irregular black surface, and an abundant fetid discharge."

The illustration of the forms of the disease would be incomplete without the following sketch from a case by Mr. Carmichael:—A gentleman, who was familiar with the venereal disease in his own person, was alarmed five days after a suspicious connexion at the appearance of a small pimple on the prepuce. Without further delay, he pinched up the part of the prepuce on which the pimple was situated, and snipped it off with a pair of scissors. The wound healed like a common sore, but he observed that the cicatrix was tender, and of a deeper colour than the surrounding skin. A month after this operation, while the cicatrix was still tender, he was again exposed to infection. The day afterwards, an unpleasant sensation induced him to examine the penis, when he perceived on the cicatrix a dark and gangrened spot, without any surrounding induration or inflammation. In four days the blackness had increased, attended with inflammation of the surrounding parts, and a disposition to phymosis. This accident, indeed, followed with considerable sloughing, aggravated by the use of mercury, which the patient insisted upon taking. The case eventually did

well, but not without the appearance of a new slough, and that succeeded by obstinate phagedenic ulceration.

The treatment of this formidable malady is extremely simple, and uniformly successful, if resorted to early. It consists in the application of nitric acid to the gangrenous surface. If this is sufficiently done, the acid, penetrating the slough, destroys the surface about to mortify, and with that extinguishes the gangrene. A poultice to separate the eschar, opium to allay pain, with what tonics and stimulants may be requisite, constitute the rest of the treatment. The patient's chance of recovery most depends upon the small extent of surface occupied by the disease; for example, the penis having sloughed, if the phagedæna has not yet spread over the pubes, and the patient has stamina left, his life will generally be preserved.

### III. OF CHANCER.

Under this head may be comprehended the various forms of ordinary siphilitic sores, or of those which are most certainly the result of siphilitic infection, and most frequently give rise to constitutional lues. The study of this class of sores is encumbered with difficulties which do not present themselves in the study of phagedæna. There is, it is true, a doubt as to the source of the phagedænic disease, and an uncertainty as to its secondary effects upon the constitution, greater both, perhaps, than attach to the parallel questions in chancre. But there is no difficulty as to the diagnosis or treatment of phagedæna; the features of each form of the disease being distinctly marked, and the practice to be pursued being deducible from the ordinary principles of surgery. In chancre, on the other hand, the local appearances do not differ from those which may arise from common inflammation: and if the opinion of surgeons throughout the civilized world were taken, it would probably be found to be pretty equally divided as to whether or not a specific treatment is requisite. The practical difficulty, however, to which I advert, will find a place for consideration afterwards; at present we shall have enough to do with that which attends the diagnosis of chancre.

In a case where a distinction is to be drawn between two diseases the appearances of which present no essential points of difference, it may be of use

to commence with examining the commoner and the easier one. Nothing is more frequent than the occurrence of a pustule and ulcer through simple inflammation; as, for instance, upon the legs of young or middle-aged persons, whose health has become deranged. In such a case, a succession of ulcers may be seen to form; the phenomena attending the production of each of which are these:—A patch of inflamed skin is seen, in the middle of which there is a small circular area of white epidermis; an appearance arising from the latter being detached from the cutis by effused lymph. In a day or two, the spot of separated epidermis is larger, is slightly elevated, and pus is contained below it. The cuticle breaking, a shallow circular ulcer is seen, the surface of which is covered by unorganized or imperfectly organized lymph. The ulcer enlarges, its figure continues circular, the tissue forming its border is more or less red and inflamed, condensed, and thickened. The surface is more or less excavated, and exhibits no granulations\*.

Now if we look for points in the appearance of a chancre, whereby essentially to distinguish it from these or other common sores, it must be admitted that there are none. Chancre can but be described as *an ulcer more or less circular, without granulations*. But it is to be added, that a chancre is a *small ulcer*; and when we inquire as to its increase, we discover that it *enlarges slowly, and has a tendency to preserve one appearance*. The latter features alone are those which enable a surgeon to discriminate chancre from many ulcers on the genital organs that are merely of inflammatory origin. An ulcer, for example, formed by herpes præputiales, may, if irritated, or even from mere neglect, assume exactly the appearance of a chancre; but in three or four days, with proper treatment, its suspicious character becomes changed for that of a healing sore. If it is not so changed,

nothing can remove the probability (derived from its place, appearance, and permanency of character) of the sore being chancre, or lessen it, except contravening circumstances in the history of the case: and, in a certain number of instances, a surgeon must inevitably be occasionally in error, and consider a sore syphilitic when it is not; as I have already shewn that he must occasionally pass over, and treat as common sore, ulcers looking like common sores, through which the venereal virus is finding entrance into the system.

I have thus carefully arrayed the difficulties which present themselves in the diagnosis of chancre, as the best means of combating them. With the qualified certainty which is consistent with the existence of these sources of error, I shall now proceed to describe the varieties of chancre, under the heads of indurated chancre, and chancre with little or no induration. I should premise, that I view the numerous shades of difference, which will be found to present themselves under these heads, as accidental only: nor should it appear surprising that so much variety, referable to accident, should present itself here. It is certain, as I have already exemplified, that the syphilitic poison may be introduced through a sore having the appearance of a common excoriation. It is likewise certain that the absorption of the poison may be attended by great local inflammatory irritation. It is, therefore, not wonderful that intermediate degrees, including all the varieties and effects of inflammatory ulcerative action, should occasionally manifest themselves. It is more surprising, all things considered, that so much uniformity and consistency should be observable as practically obtain.

I am, indeed, half afraid of indulging in the minuteness of description, upon which I shall yet venture, when the diversities presented have this unessential character. At the same time, unless the most minute examination is gone into, we can have no confidence that a really important feature may not have been overlooked; and if the subject is to be reduced to greater simplicity and certainty, it can only be through generalizations made upon a number of precise and minute details of this nature.

\* The last is an expression which it may prevent mistakes to explain. Ulceration without granulations and with no secretions adhering to the surface is seen in the cartilage of joints; and I once saw an ulcer on the instep of an old man with ossified arteries, where all the parts exposed by the absorptive process had their natural appearance; but in general, surfaces made by ulceration are covered with a layer of effused lymph, or gelatinous and adherent secretion. This effusion, properly organized, constitutes granulations. When it is not organized, or imperfectly so, the ulcer is said to want granulations.

## CONTRIBUTIONS

TO

## DESCRIPTIVE ANATOMY.

By ROBERT KNOX, M.D.

[Continued from p. 102.]

[For the London Medical Gazette.]

*The Pancreas.*

THE next pancreas I examined gave the following results:—

*Explanation of Fig. 4.*

- a. Duodenum.
- b. Blow-pipe passed through the duct, com. choled. into the intestine.
- c. Head of the pancreas or vertical portion dissected and raised up from off the long portion.
- d. Junction of the shorter duct with that of Wirsung; this junction takes place at the point where the main duct shews a disposition to divide into two ducts, as in fig. 1. (See p. 93.)

FIG. 4.

- e. Narrow twisted part of the gland.
- f. Sudden descent of the main duct (of Wirsung) behind the head of the pancreas towards the duodenum.

- g. Main duct.
- h. Bifurcation of the duct, this being its usual mode of commencing.

The pancreas I have just described male; it was rather putrid when dissected.

FIG. 5.

This view of the pancreas, which was next met with, requires scarcely any explanation. It comes, perhaps, nearest to what we may consider the normal arrangement; that is, one duct alone entered the duodenum; neither was

there any of the afferent branches entitled in any respect to be considered as the rudiment or representative of the "shorter duct." The arrangement of the next specimen was somewhat similar, but not precisely so.

FIG. 6.

I find a memorandum attached to this dissection, by which it appears that, at the time, the arrangement of the ducts seemed to me most nearly to resemble the engraving of De Graaf. On re-examining, however, that engraving, I find that there are obvious differences. In the figure above, at *a*, there was a general union of ducts from all directions, and a remarkable dipping, with sudden turns of the longer ones, which no efforts of an artist could well depict. Moreover, I find in De Graaf's text a reference made to a short tube proceeding from the main one to join the duct. commun. choled., but the artist has seemingly omitted putting the letter of reference upon the engraving. The engraving, which I copy here, will speak for itself. (See fig. 7.)

A small pancreatic branch joining the duct. com. chol. previous to the junction of that of Wirsung, has been noticed by Tiedemann. Finally, in his text, De Graaf particularly notices the small duct belonging to the head of the pancreas, and he was quite aware of its oc-

casionally entering separately into the duodenum. The criticism, therefore, of the editor of Santorini's work might have been spared; it was unfounded. De Graaf knew these structures, as seems to me, better than his critic, for he especially points out that sometimes these ducts communicate with each other by an anastomosis of their smaller branches, and sometimes they do not.

Figs. 8 and 9 are two views of the next pancreas dissected; it was that of a young man, *æt* 15. In this case the pancreas has two ducts, distinct in all respects from each other. The long duct, or that of Wirsung (*c* and *d*), was normal as to its course, and terminated with the duct. com. choled. in the duodenum in the usual way. The shorter duct was formed of branches which came mostly from the smaller pancreas; it ascended vertically, and terminated by an extremely minute orifice in the duodenum, apart from that of the larger duct, and somewhat lower down. These ducts did not communicate with each other in any way, not by their minutest

FIG. 7.

FIG. 8.

Explanation of Figs. 8 and 9.

- a. Entrance of longer duct into the duodenum, in common with the duct. com. chol.
- b. Orifice of the shorter duct.
- c. The long duct in the body of the

gland, shewing its remarkable turns, and that to neither duct exclusively does either of the larger divisions of the gland send its branches.

FIG. 9.

radicles, and thus the injection of the one could never have led to the detection or discovery of the other: I mention this as a caution to the young anatomist.

This case, then, presents the other extreme of fig. 4, and is unlike all the others; there were found two separate

and distinct ducts, completely insulated from each other, but the two great divisions of the gland did not seem on this account in any way more distinct than they are usually found to be.

Of the eighth pancreas dissected I need not give any figure, as it resembles so closely that already given in fig. 6.

FIG. 10.

The reader will easily observe from the above figure that the pancreas next examined differed from all the others in having two considerable branches corresponding with the shorter duct of Santorini (which, however, merely joined the main one), and in presenting at the narrow and twisted part of the gland a considerable branch.

In Part II. I shall consider the arrangement of the pancreatic ducts in the fetus, and in a few of the higher orders of the vertebrata, but subjoin here fig 11—a figure of the exact form of the human pancreas, when merely cleared from the surrounding parts.

FIG. II.

M. Cruveilhier's opinion\* that the pancreas gradually narrows from its duodenal to its splenic end is manifestly incorrect; he seems disposed to give the name of "smaller pancreas" to that portion of the gland which passes behind, and in some measure around, the mesenteric vein. My own dissections do not confirm M. Cruveilhier's opinion that the duct of Wirsung, "par une disposition unique dans l'économie, est contenu tout entier dans l'épaisseur, on peut même dire, au centre de la glande;" on the contrary, the duct may be reached, from the posterior surface of the gland, without cutting into its texture. The expressions used by him respecting the ducts are not sufficiently precise. "Le canal excréteur est quelquefois double, et lors il y a un canal principal qui appartient au corps même du pancreas, et un petit canal qui appartient à la portion réfléchie, ou petit pancreas†." I have not found that the smaller duct, when present, can be considered as belonging exclusively to that portion of the pancreas to which he has given the appropriate enough name of the "reflected portion."

Again, I have not found that the long canal augments progressively as it ap-

proaches the duodenum\*, nor that the duct, com. choled. and pancreatic canal open constantly by a single orifice into the duodenum.

My object being merely to offer contributions to the correct anatomy of the human pancreas, I may be excused noticing more particularly for the present the writings of Meckel, Morgagni, Wharton, Winslow, and others. Meckel, who is in general a most exact anatomist, is not so happy as usual in his description of the pancreas; he commences by saying that it is six inches long and one inch thick (p. 473.) He quotes a work on the Fœtal Pancreas (Abhandlurgor, 331 to 386), which, no doubt, must be valuable: I regret not having been able to procure this work. The occurrence of two ducts in the adult pancreas he considers as merely a persistence of the fetal condition of the organ. Professor Tiedemann published, in the "Journal Complémentaire," t. i. p. 330, a very learned paper "On the differences which the excretory canal of the pancreas presents in man and in other mammalia." This paper by Dr. Tiedemann, like all his other writings, may be consulted with great advantage by the student. The very first dissection recorded refutes an opinion of M.

\* Anatom. Descript. du Pancreas, t. ii. p. 591.

† Ibid. p. 595.

\* Ibid. p. 593.

Cruveilhier, that when two separate excretory ducts exist, one must necessarily open into the duodenum along with the duct. commun. choled.; in Tiedemann's case this did not happen. It must be admitted, however, that both orifices were very close to the entrance of the biliary duct. Dr. Tiedemann seems to be of opinion, that when there exist two separate pancreatic ducts, the larger must necessarily unite with the biliary duct; but dissection 1st of this memoir refutes this view. It is almost needless to remind the anatomist, that all the varieties occurring in the arrangement of the ducts of the human pancreas are supposed to be reducible to two categories—viz. fetal structures persisting to the adult state, or a repetition of what occurs in the lower animals. A very singular variety, which I have not met with, is described by De Graaf at page 517:—"Reperimus tamen in homine eos ita constitutos ut unus cum altero non jungeretur, licet uterque ad extremum pancreatis eadem fere longitudine ac magnitudine extenditur." This extraordinary length of the usually shorter duct I have not met with.

In conclusion, then, I may be permitted to say, that the language of most anatomists in respect to the duct or ducts of the pancreas is vague, and has led to nothing accurate. If by *two* ducts they mean two ducts running parallel, and nearly of equal length, then they speak of a structure so rare that I have never seen it, neither in a fresh dissection, nor preserved in any museum. If, on the other hand, by *two* ducts, they mean a short and a long one, and that the former belongs to the head of the pancreas, or the smaller pancreas, the latter to the larger and longer portion of the duct, then again their language is altogether incorrect; for when there exist two separate ducts in the pancreas, they not only vary in direction, origin, course, and connection, but it can be demonstrated that neither is exactly limited to either of the great divisions of the gland. In my next memoir I shall examine into the accuracy of the German hypothesis, which endeavours to explain some of these anomalies by the persistence of the fetal structure.

## OBSERVATIONS ON PUS.

BY GEORGE GULLIVER, F.R.S.

Assistant Surgeon to the Royal Regiment of Horse Guards.

[For the London Medical Gazette.]

As it is my intention soon to publish a second section of my researches on suppuration, I propose merely on the present occasion to offer a few extracts from my notes, with remarks, in relation to the valuable observations by Mr. Mayo in the last number of the MEDICAL GAZETTE.

The pus-like globules seen by Mr. Mayo in the blood of healthy persons are probably the same as those mentioned by M. Magendie in his lectures, as the large white globules of the blood, and since noticed more particularly by Dr. Davy, in his *Physiological and Anatomical Researches*, just published by Messrs. Smith and Elder.

I have long been acquainted with the white globules; and at an early period of my inquiries often confounded them with those of pus, an error which a more accurate examination soon enabled me to avoid. In a communication submitted to the Royal Medical and Chirurgical Society, last March, "On the Composition and Elementary Structure of the Pus-Globule," I detailed the action of various reagents on this body in a manner which appeared to me calculated to establish its distinctive characters; and I have since learned that Dr. Ludwig Guterbock, in a very ingenious and original dissertation, had previously pointed out the compound structure of the pus-globule. The following notes are from my paper, of which a short notice was given in the MEDICAL GAZETTE for May.

EXP. I. *Action of sulphurous acid.\**  
—On adding it to pus, no effect was apparent to the naked eye but dilution. A portion of the mixture was examined with the deep object-glass, when each globule was plainly perceived to be a compound body, viz. two or three spherical molecules centrically inclosed in an external part, the latter being apparently a little distended, and rendered

\* An interesting account of the action of sulphurous acid on the animal textures is given by Dr. Davy, in the 3d vol. of the *Edin. Med. Chir. Transactions*.

so pellucid, as to allow of the former being observed very distinctly. The diameter of the molecules was from 1-10666th to 1-8000th of an inch.

Exp. 2. *Action of sulphuric acid.*—When mixed with a little pus the fluid became of a deep purple colour, and the pus appeared to be dissolved. On microscopic examination, however, the mixture was found to be pervaded by numerous little smooth spherical molecules, hardly one fourth the size of the entire pus-globule. They were not altered by keeping the mixture, nor by subjecting it to the heat of boiling water.

Exp. 3. *Action of acetic acid.*—The molecules were easily seen by the action of acetic acid. When the pus was quite recent, the external part of the globule was quickly dissolved, leaving the molecules quite bare; but if the pus had been kept a while, the external part of the globule was not perfectly soluble in the acid, although the molecules were immediately exposed by it.

Exp. 4. *Indisposition of the molecules to change.*—A quantity of the molecules obtained from recent pus by acetic acid were treated by repeated abluitions with rain water. They stood for months in a room at an average temperature of 60° without any change whatever, or the slightest signs of putrefaction. They seemed very dense. They were not affected by acetic acid at the temperature of 212°, nor by the addition of an excess of boiling water to the mixture of acid and pus. If pus be kept for some months, the external part of the globules will be more or less destroyed, but the molecules will remain entire, either connected together, but easily visible through the remains of the surface, or floating about separately in the fluid.

Exp. 5. *Action of water on the recent pus-globule.*—Take a little gonorrhœal matter, fresh from the urethra; the diameter of most of the globules will be from 1-3000th to 1-2666th of an inch; add some rain water, when they will become perfect spheres, which they were not at first, and so swelled as to present a diameter of 1-2000th of an inch, or even larger.

I at first thought this change peculiar to the globules of clap-matter; but I have often since seen the same phenomenon in recent pus from other parts.

have not hitherto been printed in detail, exhibit some of the essential characters of the pus-globule. On their accuracy in this respect rests the greater part of the evidence on which I have founded my observations, “On the frequent presence and on the effects of pus in the blood, in diseases attended by inflammation and suppuration\*.”

As I hope to be able, shortly, to publish the results of an inquiry, in which I have been long engaged, concerning the nature of the white globules before mentioned, it is unnecessary to enter into the subject here. I have frequently examined them in birds and reptiles, from which it is to be inferred that these globules are distinct from those of pus. Dr. McDonald† could not induce suppuration by any degree of injury in pigeons; nor have I ever been able distinctly to establish this process in reptiles, notwithstanding that statement of M. Gendrin, in which he assures us how easy it is to see the formation of pus globules in the web of the frog's foot.

Relative to the size of the pus-globule, the fifth experiment points out a source of fallacy. The diameter is, indeed, so variable, that scarcely any measurement has ever been given which might not be verified in almost any specimen of pus; and the same observation is equally applicable to nearly all the measurements which have been published, of the human blood corpuscle. If, however, we are to consider the individual diameter of the greatest number of globules, as seen at any one time in the field of a deep object-glass, I should have no hesitation in asserting that I have never seen them, in pure pus, so large as 1-2000th of an inch, though I have occasionally observed a few larger. Thus, in some pus from a chronic abscess in the neck, I have the following note: “almost all the globules, from 1-3000th to 1-2500th of an inch—but there were several much smaller, not more than 1-4000th,—while in one field two were observed respectively of 1-1714th and 1-1600th of an inch; there were, besides, numerous pus-molecules from 1-12000th to 1-8000th of an inch in diameter.”

I would venture to express a hope that Mr. Mayo will continue his observa-

\* London and Edinburgh Philosophical Magazine, Sept. 1838.

The preceding experiments, which

tions on suppuration; and I am glad to see that Mr. Lane too is directing his attention to this interesting subject. Dr. Davy observes, with much truth, that "inquiry is now happily directed to pyogenesis, and with the aids which the collateral sciences are capable of affording, there is good ground to hope that its termination will be successful; and, if successful, that it may be the commencement of a new era in pathology\*."

ON THE IMPORTANCE  
OF ATTENDING TO  
THE PREMONITORY SYMPTOMS  
OF INSANITY;  
*With Cases.*

BY JOHN GRANTHAM.

[For the London Medical Gazette.]

To judge by the many admirable productions of the most distinguished writers upon the subject of insanity, it might be naturally supposed that few, or none, of the medical profession could be very deficient in a knowledge of that malady, and were the question proposed perhaps no one would have the modesty to confess his ignorance of a disease which has, however, been the means of casting repeated and well-merited opprobrium upon the whole profession. "Every one knows how little value is attached to the evidence of medical men in cases of lunacy, on account of the wild and fanciful notions which they often bring into court with them. In common practice, if insanity declares itself, and resists bleeding, blistering, and purging, all the anxiety of the practitioner is to get the patient out of his hands, and to send him, no matter where, so that he sees no more of him; and we can ourselves testify, from personal observation, that a nervous patient may be taken from the practitioner who has been in attendance, dragged, under the most unfavourable circumstances, before another, sentenced to confinement among lunatics, and placed beyond the possible means of immediate liberation†".

When we reflect upon the consequence of such ignorance, among a class of men whose office is directly associated with the worst personal, relative, and social evil that can afflict humanity, we may, indeed, be alarmed at the responsibility we each incur in our decisions upon and treatment of the insane. In such cases it is not enough that a medical man do the best he can for his patient; he should be able to do the best that *can* be done, and in the majority of cases very much may be effected; not unfrequently, indeed, the patient be delivered from impending insanity, by rightly comprehending its premonitory symptoms; and if we reflect that beyond their boundary is madness, when the wretched patient will be submitted to the slender chances of recovery in a lunatic asylum, how deeply anxious should we not be to rescue him from such an extremity.

To arrest the approach of death, and to reinstate our patient within the circle of the living, demands no ordinary powers, but to wrestle with the premonitory warnings of madness, and to deliver the sufferer from the bondage of a living death, calls for the exercise of our highest faculties, and most extended means.

The duties of the general practitioner, in cases of insanity, are chiefly limited to the treatment of the premonitory symptoms; it is at that time when the patient stands, as it were, on neutral ground, that the practitioner is sent for; at a time when he is surrounded by relatives and friends, and the soothing attentions of home—circumstances often the most favourable for the sufferer\*. But with these advantages, a very frequent cause of error in the judgment of a medical man (when called upon to decide as to the state and probable restoration of the patient) is the undue regard which is paid by him to the wishes and opinions of the friends, who seem to take a pleasure in enlarging upon the odd whims and irregularities of the patient; the fears of one party and the ignorance of both soon settle the question, and at once precipitate the poor sufferer from a state of comparative sanity into irremediable madness. A medical man will do

\* Physiological and Anatomical Researches.

† See the British and Foreign Medical Review, No. xii. p. 3.

\* "C'est souvent," says M. Esquirol, "dans le premier mois qu'on obtient le plus grand nombre de guerisons," and which opinion is confirmed by Pinel.

well to prefer even the unmethodical relations of the patient rather than trust to the opinions of friends, for how often is it that actions seemingly the most whimsical may be strictly consistent with the physical condition of the invalid; thus insane persons tormented with feverish heat delight in exposing themselves to cold air or water, while, as M. Esquirol observes, a disordered state of the digestive organs oftens renders them (the insane) averse to taking food.

Avoiding all opinions that are prompted by the timidity or ignorance of the relatives, the practitioner will possess a most valuable agent in the advantages of home; but while he will necessarily avail himself of all the moral agents, the great evil is lest too much should be trusted to them. If the tongue be clean, the pulse regular, and the evacuations natural, the patient is too often comforted with a mild soothing remedy, and a few soothing words: he is encouraged not to foster whims and fancies, and thus the farce goes on until it ends in permanent mental derangement. The result brings no reproach upon the practitioner; the very definition of the term *mental derangement* acquits him of ignorance or neglect. We are little aware how much confusion arises from wrong definitions, and in no instance is this truth so forcibly exposed as in the ill-defined and misunderstood term *mental derangement*. Sudden terror or protracted grief act upon the brain and nervous system, and end in madness; the brain responds to the mental action, and becoming deranged reflects upon its agent the evil it has received; and thus mental derangement, though caused by the mental influence, is a subsequent effect of its own operations. If this definition were always kept in mind, any objection to the term would be impertinent; but the practice of regarding insanity as simply a disease of the mind, and which the state of the patient's general health will frequently corroborate, has led to the worst consequences in the treatment of the insane. Such a definition, with medical men, unless carefully explained, will be prejudicial to the success of their plans. It should never be forgotten that what is true in psychology may be false in physics.

From pecuniary losses, or domestic dissatisfactions, a man becomes dejected, or irritable, abstracted, melancholy, ner-

vous, or ultimately mad; the primary cause of his madness is justly said to be mental, but the effect is manifested by bodily disease, and if not always to be detected, yet not the less certain is it, as M. Esquirol remarks, "that the chances of cure in insanity, but especially in melancholy, always offer more hope when we are able to perceive some disorder of the function of assimilative life."\* The same is observed by the author of that very able review in No. XIII. of the British and Foreign Medical Review. "We grant that the mental malady may often be but the first sign of that total impairment of the frame which phthisis, or hydrothorax, or scorbutus, or paralysis, or marasmus, afterwards more plainly declare; but we suspect that there are cases in which, if the life of the patient were preserved through some of the maladies supervening on the mental disorder, the mind would be found to be restored, and the malady to be critical."† This opinion affords a most encouraging confidence in the possible cure of almost all cases of incipient lunacy, and could we but enlarge our faculties, so as to trace out the organic and functional changes in the various states of insanity, as in other diseases, there would be little to apprehend from its continuance. Happily for the patient, the time when he consults his physician is the time best adapted for medical aid: the patient is capable of describing his own feelings, he knows that something is wrong, and he often takes a melancholy pleasure in the relation of his minutest sensations—it is then that the medical attendant must be observant, acute, forbearing, and most anxiously solicitous, if he would save his patient, and with the nicest caution avoid every appearance of indifference, nor repress the anxieties of the sufferer by the assurance that he is nervous, fanciful, or whimsical.‡ Consistent with the preceding opinions the *materia medica* will always furnish its

\* Forbes, vol. i. p. 476.

† See page 39.

‡ La conduite du médecin doit toujours être grave, la plus scrupuleuse justice doit caractériser ses ordres. Jamais il ne doit plaisanter les malades sur les idées fausses qui les tourmentent: c'est un moyen sur de les exasperer.

Jamais non plus il ne caressera leurs chimères, mais écoutant avec patience les plus minutieux détails de leurs peines, il tâchera de convaincre ces malheureux qu'ils ont maladies, et que tous ses efforts ont pour but de les guérir.—Forbes.

aid to that of the moral agents. It is better that medicine should even create a disease, than to resign its agency from an opinion that the case is altogether a mental alienation.

To allay the irritabilities of incipient insanity is certainly a *désideratum* in medicine, and we wish we could entertain the consolatory belief possessed by Sir W. Ellis, that "there is in nature some undiscovered medicine that would act as a specific in these cases." Whether such a catholicism can exist or not, is indeed doubtful; but that remedies correspondent to the nature of the disease may be procured there is no doubt. On being called upon to attend a case of incipient insanity, what is the plan to be pursued? This is the question which every one would naturally propose to himself, and which of course involves the issue of the case. The first consideration should be, that mental derangement implies bodily disease\* in some form or other. With such premises the medical man must inevitably circumvent the whole case in all its relations, neither omitting nor trusting too much to the moral treatment, while he is on the alert to apply the most efficient medicines. The conduct and treatment of the medical man must be directed entirely by the cause, character, and violence, of the malady; if a disease of excitation, or depression, or vivid hallucinations, or drowsy apathy—whatever be the state, the physical appearances will sure to be coincident with the force and nature of the affection. The bodily organs soon yield to the mental suffering, and by their very derangement furnish the best possible suggestions to the physician, and in many cases the most effective antagonist to the disease. It is chiefly from this cause that the medical plan is more available in incipient than settled insanity: in the active and conscious struggle between reason and madness the health always suffers, but with absolute insanity the mind loses all its former recognitions: those previous anxieties and forebodings disappear with the mental consciousness, leaving the patient in that state of utter apathy or frivolous activity which is often most

agreeable to the general health\*. It becomes, therefore, a matter of the highest importance to attend to those never-failing physical indications which characterize incipient mania: further than these first principles it would be useless to speculate upon the premonitory symptoms of insanity. "Quel est celui," says M. Esquirol, "qui pourrait se flatter d'avoir observé et de pouvoir décrire tous les symptômes de la manie même dans un seul individu?" Every thing must be left to the occasion, and however intricate and obscure the disease may appear, much if not all may be effected by a steady and critical examination of the case, personal and relative. The following cases will perhaps better serve the object of this paper than all that could be further said upon so involved and expansive a subject as the premonitory symptoms of insanity.

In describing the following cases I feel some difficulty in stating the particulars of the treatment, as they are written from memory, with the assistance of but imperfect notes.

CASE I.—Jan. 6th, 1832. I was consulted in the case of W. C., of Greenwich, employed in an oil and colour shop. In stature he was short, temperament melancholic; complained of great depression of mind, inability to rest, loss of affection for his wife and children, which he appeared greatly to regret, and a sense of insufficiency to perform any act. His medical attendant considering it the most advisable step to send him to a lunatic asylum, accordingly wrote, or offered to write, a

\* Shakspeare, with his usual philosophical accuracy and profound observation, has strikingly illustrated this truth in the passionate reasoning of Constance:—

*Pandolph.*—Dady, you utter madness, and not sorrow.

*Constance.*—Thou art not I o!y to belie me so; I am not mad: this hair I tear is mine; My name is Constance, I was Geoffrey's wife; Young Arthur is my son, and he is lost; I am not mad; I would to heaven I were! For then 'tis like I should forget myself. O, if I could, what grief should I forget! Preach some philosophy, to make me mad, And thou shalt be canonized cardinal; For being not mad, but sensible of grief, My reasonable part produces reason—How I may be delivered of these woes; And teaches me to kill or hang myself: If I were mad I should forget my son; Or madly think a babe of clouts were he: I am not mad: too well, too well I feel The different plague of each calamity.

\* Ainsi on peut établir que la plupart des causes de la folie agissent en excitant le cerveau.—*Forville*.

certificate to that effect. His friends not being satisfied with such an alternative, requested me to see him. I found great torpor of the liver, an intermittent form of fever, erysipelatous inflammation of the integuments covering the head, the vessels of the tunica conjunctiva injected with a yellow fluid, the urine copious and pale. The mouth was made sore with mercury, which tended only to render the paroxysms more distinct. On examining the chest, the sternum was much depressed, the action of the heart feeble, the region of the liver free from tenderness: in the epigastric region the stomach was found developed, extending down to the umbilical and left iliac regions. I ordered him a spare diet, with two drops of the hydrocyanic acid, three times a day, increasing the doses gradually, until he took fifteen drops in the day, which finally procured four good nights' sleep. His mind resumed its tranquillity, and he felt able to attend to his employment. The senses of hearing, smelling, and seeing were natural, but the senses of tasting and feeling unnatural. He continued improving. Nov. 4, 1832, his friends informed me he had remained well, filling up his time with active exertion, and is, up to the date of this paper, enjoying good health.

CASE II.—In relating the case of this patient, Mrs. F—r, it may be right to observe, first, that previous to her marriage, in 1830, I attended her in consequence of an affection of the brain. She did not speak for seven months, during which time the circulation was not disturbed; there was functional derangement of the stomach and intestines, attended with great constipation of the bowels; the rectum appeared quite inactive, in spite of stimulating injections. She occasionally refused food, and fasted a most extraordinary length of time; the catamenia ceased, and, as it afterwards proved, from pregnancy; thence a cause for the hysterical mania. Since this time she has been the mother of three children, has conducted herself with great propriety under the most trying events of life, until January 23, 1837, when, from excessive grief for the loss of a child, a low type of fever came on, accompanied with great vitiation of the excretions and loss of flesh. At this time she became

pregnant, and appeared to rally, recovering her strength so as to enable her to take moderate exercise.

On the fifth of February, 1837, she was attacked with mania, attended with refusal of food, and loss of one or more of the faculties of the mind, without any perceptible disturbance of the sensations or voluntary motions. There appeared to be no one subject on which she might be excited. The paroxysms gradually became more and more severe. I gave large doses of tartarized antimony, and bled generally and locally, never exceeding ten ounces of blood at one time. The hair was cut short; cold and hot applications were tried to the head; blisters along the spinal column, dressed with strong mercurial ointment. For aperients, I first gave doses of six grains of calomel, with the sulphate of magnesia, which had no effect; the croton oil; also injections of hot water, containing salts, turpentine, castor oil, &c. By these means the bowels were relieved about once in forty-eight hours; the urine passed involuntarily. I next gave two drachms of the aromatic spirit of asafetida three times a day, which unloaded the bowels copiously; the bladder regained its tone; she increased in strength, her memory returned, and she took food by the month, having been previously fed with liquids through the nostrils by means of a funnel, and injections of beef-tea, &c. per anum. During this treatment, which lasted about five weeks, I kept the husband and family away from her; but on the 26th of March, finding her so much restored, and she having a desire to see her husband and children, I allowed it, with the hope of improving the better feelings of the mind. On the evening of the same day, to the end of seven days, she lost all memory, became most violent, using the most horridly obscene language, eating her food voraciously, again passing the urine involuntarily, and bowels not acting for five days, notwithstanding the daily use of injections. I repeated the use of asafetida, which had the same beneficial results as before; her mind became more tranquilized, and on the 16th of August she gave birth to a fine healthy child. Three days after delivery reason once more returned, and my patient, up to the present time, has remained in perfect

health of mind and body, and is anticipating the birth of her fifth child in September.

CASE III.—Dec. 26th, 1837, I was sent for to visit a Mr. G. L—y, whom I found almost naked, in a state of excitement, labouring under great uneasiness, his ideas incoherent and incongruous, with unusual gestures, now and then bursting into a frantic state, exclaiming “System! system! I want system!” On inquiry into the cause of this sudden fit of insanity, I learned he had been in a very melancholy state of mind for two years, having previously imbibed the doctrine of the justifiability of suicide. The pulse was quick and hurried; tongue white and dry; skin hot; the eyes inflamed. I administered ten grains of tartarized antimony in his tea, which required to be repeated in two hours. After the second dose he became tranquil, but was evidently suffering from the most agonizing feelings of mind. He was now bled to the extent of sixteen ounces, and afterwards in small quantities, according to the hardness of the pulse: he also underwent a gentle course of mercury, taking the tartarized antimony, with small doses of sulphate of magnesia, according to the severity of the stages of excitement, which assumed an intermittent form. I forbade reading and conversation, but enjoined exercise of the body, especially gardening. In three months my patient became quite tranquil. I now requested him to go to sea, quit all his associates, and endeavour to forget the past, and contemplate the works of creation. This has happily proved of great service. I heard from him about two months ago; he was then off the Isle of France, in excellent health and spirits. It is just to observe, that when he left this place, as he felt the tendency to excitement, so he took the ant. tart., with the sulphate of magnesia, until the feeling subsided.

On further inquiry as to the moral cause of this condition of mind in a subject apparently so healthy, and descended from sound parents, I learned that he was placed as an apprentice, at the age of 14 years, to a carpenter and joiner, at Rotherhithe, who frequently in the presence of my patient held conversation with another man on the justifiability of suicide. My patient then

perused deep tragedy, making notes or comments on all those parts of the drama that refer to suicide. He also studied the science of music, and afterwards he had his mind excited with some lectures of Carlisle's, Macconnel's, &c. at the Rotunda, Blackfriars' Road, thereby living a life of undue excitement, which unfitted him for the duties which devolved on him in his station of life. Feelings of vexation and disappointment preyed on his mind; he sunk into a rooted distrust and hatred of mankind. It may also be interesting to add, that the individual who first sowed the seeds of the suicidal principle in the above case, himself committed self-destruction.

CASE IV.—About the year 1830 I was asked by a medical friend to visit a patient, Mr. T—s, who had been under the care of two other medical men, who considered his case one of mania. I found the patient a tall spare man, of a melancholy temperament; in conversation gloomy and distrustful, with a full power of memory. His skin dry; bowels clayey and very offensive; urine scanty and high coloured; fever of a remittent character, with typhoid tendency; pulse frequent and feeble; the senses of hearing and seeing natural; smelling, tasting, and feeling depraved. The subject which had occupied his thoughts more than any other was the hyper-calvanistic sentiment, which he had imbibed with all the poison of bigotry. The difficulty of reconciling the unlawfulness of the act of living with another woman, his wife (whose character was not free from blemish) being alive, caused impressions in his mind which so disturbed the other feelings as to cause a profound state of despondency. I enjoined a light nutritive diet of animal food, in solution, barley water, gruel, &c. every two hours, in small quantities; to maintain the recumbent posture, and the temperature of the feet to be attended to by means of a foot bath; the internal exhibition of calomel, with small doses of tartarized antimony, every three hours, according to the state of the stomach and bowels, and friction to the abdominal region, with the unguentum antimoni tartarizati. In the course of seven or eight days black offensive mucous discharges were passed from the

bowels; the mind became more active; the strength began to return; and the fever assumed more of an intermittent character. I now ordered the quina to be given between the paroxysms of fever, which afforded him much benefit, yet a considerable restlessness of mind remained, and although the health was so much improved there was evidently an enlargement of the liver. At this stage I suggested his being removed to another place, it mattered not where, as a change of scene was necessary to give a turn to the moral feelings, and remove him from those surrounding objects which had been excitants in the commencement of his affliction. With this last injunction he did not comply, his health sank, he became a complete monomaniac; all hope in a future state being denied him. His pecuniary circumstances left no alternative but a lunatic asylum, to which he was taken, and in which he died within a few months of his admission.

CASE V.—John —, a printer, about 48 years of age, whose family had suffered from mania, was addicted to excessive and long continued acts of intemperance. He possessed great mechanical power, and was considered a very superior workman; poverty was no incentive to duty; he would drink while money lasted or credit could be obtained, and to such an extent were his acts of inebriety carried that his family were compelled to seek parochial aid, which led to his removal to a lunatic asylum at Peckham, from whence he returned cured after two months' confinement; he then continued well for about six months, working at his employment; again he resorted to his old habit, and in one of the excitements (Feb. 15th, 1832) he divided the trachea, anterior portion of the pharynx, and some branches of the lingual arteries, with a razor. After tying the vessels, the head was brought down towards the chest, and I forbade his making any effort to swallow; on the third day I tried to pass a long elastic gum tube into the œsophagus through the nostrils, but it returned through the wound. He was sustained by means of injections of beef-tea, gruel, &c. per anum, which supported life until the opening in the pharynx closed, which was effected by the 18th of March. The fluids could

now be made to pass into the stomach with the assistance of a pad of lint to the wound so as to exclude the atmospheric air, and cause the glottis to act. On the first admission of food into the stomach, gastric irritation supervened, which was relieved in a few days by occasional doses of ten drops of laudanum, and a drachm of carbonate of soda. He again became tranquil, in which state he remained about nine or ten months; but at the expiration of this period he relapsed into his old habit. His wife, to prevent his being sent a second time to an asylum, suffered every privation, and actually died, owing to the weight of her cares. Even this melancholy event had only a temporary effect. He a second and third time attempted suicide; on the latter occasion by jumping into a well. During the interval of these paroxysms I frequently pointed out to him the necessity of attending to the early symptoms of excitement, and he at last consented to allow me the power to act when I thought proper. Accordingly I requested his family to give me early intimation when he commenced drinking, so that I might have him brought home, and watched by an able attendant. Since he has allowed me this power I have in the first twelve hours of the attacks administered repeated doses of the Tart. Ant. cum Sulp. Mag. in doses of from six to ten grains of the antimony, to two drachms of the sulphate, which always had the effect of quieting him, and allowing of future treatment, without any further need of control. The management of the case then consisted in giving him Soda Carbonas and Spirit Ammon. Aromaticus in large doses, with a bland nutritive diet. It must be remembered that the mucous membrane of the intestines of such men is generally in an irritable condition, and if pain or tenderness in the epigastric region, with a hardness of the pulse, came on, I have taken six to eight ounces of blood from the arm. By a repetition of this treatment my patient is now able to support his family, and has also by frugality made some reserve for declining life.

Crayford, Kent, Sept. 30, 1839.

## SMALL POX AND VACCINATION.

To the Editor of the Medical Gazette.

SIR,

IT is certainly much to be regretted that an error, or rather a series of errors, such as those which I pointed out in my last communication, should have occurred in Dr. Baron's report, because it leads naturally to the inference, that the same "hurried and broken manner of carrying on the inquiry," to which Dr. Baron attributes one imperfection, may have led to others. My present object is to point out, not an error of fact, but what I believe to be an error of conclusion from a fact.

Dr. Baron has stated very clearly (at page 26) Mr. Ceely's recent experiments at Aylesbury, which have clearly demonstrated, that the cow will receive the infection matter of variola from man, and *convert it into vaccine*. Dr. Baron then proceeds to say, "this highly valuable information cannot fail to have a most salutary influence. The right understanding of this question, both by the profession and the public at large, will, we are assured, greatly tend to remove the prejudices which still exist; to secure correct and satisfactory practice; and enable us to speak with confidence respecting its nature and object, as well as of the protection which it (vaccination) affords." "Well may we now say, to use the language of Jenner, that vaccination is placed upon a rock, and that, if properly conducted, it will secure the constitution as much as variolous inoculation possibly can."

It appears to me, sir, that these conclusions savour somewhat of hurry, and that they have been penned without that caution and careful deliberation which the importance of the subject demands. Of the value of Mr. Ceely's experiments, as a most interesting addition to the pathology of vaccinia, no one is more fully sensible than myself; but I am wholly at a loss to imagine how these experiments are to *remove prejudices*; by what means they are to *secure correct and satisfactory practice*, or in what way they are to convince us that vaccination and variolous inoculation are *on a par*, in respect to their power of securing the constitution from the further assaults of variola.

First, as to the removal of prejudices. Whatever prejudices against vaccination exist, must be on the part of the world in general, not on the part of the profession. Dr. Baron admits (page 76) "that the confidence of the profession at large in the virtue of vaccination is unshaken." Surely it cannot be said that existing prejudices in the public mind have had their origin in any doubts as to the pathology of cow-pox. But even if they did so arise, Mr. Ceely's experiments could hardly remove them; for by Dr. Baron's own showing (Report, p. 10) they only corroborate the opinions of Jenner—opinions which have now been before the world for forty-one years; independent of which, we have Dr. Baron's own authority for saying, that for the last eight years at least no such doubts and misgivings ought reasonably to have been entertained.

On the 21st November, 1831, Dr. Baron addressed a letter to you (to be found in the *LOND. MED. GAZ.*, vol. ix. page 301), wherein, after alluding to Dr. Sunderland's experiments on the infection of cows with variolous effluvia, he uses the following strong expressions:—"Since that period," meaning the death of Dr. Jenner, "the great problem touching the origin of the variolæ vaccinæ *has been solved*; and the soundness of Dr. Jenner's views has received *the most signal corroboration*." Again, he asks, "How has the conviction on the mind of Jenner, as to the identity of small-pox and cow-pox, been strengthened and demonstrated?" The interesting fact recorded by Dr. Sunderland is *demonstrative* of the truth of the conclusions which have been mentioned. The difficulty which I experience is in understanding how Mr. Ceely's confirmation of a fact which, on Dr. Baron's own shewing, had been proved and demonstrated nine years ago, and invariably taught and urged by Dr. Jenner from the first announcement of vaccination, is to have the effect of overcoming prejudices which still exist.

Still less am I able to perceive how these experiments are to succeed in *securing correct and satisfactory practice*. The careful practice of vaccination is surely independent of all theoretical speculations on the origin of the vaccine virus; and if a practitioner

should exist who still withheld his assent from the pathological dogma, he would nevertheless be equally anxious to secure a correct and satisfactory result. The establishment of a general penny postage, by the facilities it will afford of supplying the public with vaccine lymph, both abundant in quantity and from various sources, will do more to secure correct and satisfactory practice than the solution of twenty pathological problems.

I come now to investigate that presumed third effect of Mr. Ceely's experiments, viz. that they will enable us to speak with confidence of the nature and object of vaccination, as well as of the protection which it affords.

At page 39 of Dr. Baron's report, you will find it thus written:—"As long as doubts existed respecting the character of the disease derived from the cow, as long as it was a question whether it was of a variolous nature, it was impossible to predicate with any certainty whether it was likely to afford a permanent or a transient protection." I read over this passage two or three times, before I could persuade myself that it was written by the author of the life of Dr. Jenner. One of the chief designs of that work was to shew, that no reasonable doubts could have been entertained on the subject; that the early observations of Jenner, on the permanency of vaccine protection, were of themselves sufficient to satisfy any man, and that the labours of his successors proved the doctrine amply and satisfactorily, twenty years before the experiments of Dr. Sunderland on the infectious communicability of small-pox to the cow, and thirty years before Mr. Ceely demonstrated the communicability by inoculation. I will trouble you only with one extract. At page 278, vol. i. Baron's Life of Jenner, the author, after commenting on the strong expressions (as to the permanency of vaccine protection) employed in 1825 by the Royal Academy of Medicine of Paris, states his own opinion in these words:—"After the most mature examination, it cannot be doubted that this process, when duly gone through, does certainly afford as complete immunity from subsequent attacks of small-pox as that disease itself can do. Indeed," he adds, "if I were to be guided by my experience in this district, I would say that cases of failure have been so rare,

as to justify even a stronger statement of the protecting qualities of cow-pox." Surely this is predicating with some certainty; it is "speaking with some confidence respecting the nature and object of vaccination, and of the degree of protection it affords." Doubts regarding the intimate nature and variolous origin of vaccinia either existed at that time, or they did not. If they did then exist, these deductions of Dr. Baron were premature, and ought not, according to his own statement, to have commanded our confidence. If they did not exist, then Mr. Ceely's experiments are *surplusage*, and cannot, therefore, reasonably be expected to produce those valuable results, both to the theory and practice of vaccination, which Dr. Baron's report anticipates.

Your obedient servant,

GEORGE GREGORY.

31, Weymouth Street,  
Oct. 28, 1839.

---

*To the Editor of the Medical Gazette\*.*

SIR,

MANY of your readers who are interested in the inquiries going on respecting small-pox vaccination, must have read the Report of the Vaccination Section of the Provincial Medical and Surgical Association with much surprise. It is therein stated (page 65), in a quotation from the work of Mr. Cross, of Norwich, "that out of 603 persons affected by that disease (variola), 297 had previously had small-pox." Their surprise will have ceased on reading the letter of Dr. Gregory, in last week's Gazette, in which it is shewn that the 297 persons mentioned by Mr. Cross as having been previously inoculated, and composing part of 112 families, had no eruptive disease at all during the Norwich epidemic, and that the passage in the report of the Provincial Medical and Surgical Association is altogether a misquotation from Mr. Cross's work.

Now I should like to ask whether it is not a most shameful and unpardonable blunder on the part of the gentlemen composing the committee of the Medical and Surgical Association, of which Dr. Baron is chairman, to allow

---

\* We insert this letter, which was received too late to publish last week, because, although it was answered as to one point, by Dr. Baron, in our preceding No., yet other important questions are touched upon.—ED. GAZ.

such an error to be published to the world, to mislead the profession and the public, in a point of such pathological and vital importance. Small-pox after small-pox is well known to all the intelligent and well-informed of the profession, to be of *very rare* occurrence indeed, and I should like, also, to ask Dr. Gregory, who is pretty well acquainted with the literature of his profession, especially that part of it belonging to small-pox and vaccination, why he allowed such a gross error to be published, as I see his name on the committee of the Medical and Surgical Association, as well as that of Mr. Cross himself, Dr. Conolly, &c. &c. and hence a guarantee is given to the profession that the literary part of the report has been carefully drawn up; and I also see that both Mr. Cross and Dr. Gregory were at the association meeting at Liverpool, and must have had an opportunity of knowing the contents of that report.

As chairman of the vaccination section of the Provincial Medical and Surgical Association, Dr. Baron is, doubtless, the responsible person; but unless the committee were to have a voice in the report, why not make Dr. Baron at once the Alpha and Omega of the section. We have had enough of his laudation of Jenner year after year; we want now to arrive at the real merits of vaccination.

If we except the valuable experiments of Mr. Ceely, of Aylesbury, I really do not see that the Provincial Association has advanced one step in support or illustration of vaccination. "The impression" and "strong belief in the efficacy of vaccination," reported by Dr. Baron from different medical practitioners, are of little value; we want *facts*; we want some carefully drawn up statements to corroborate these beliefs. It is not enough for the thinking part of the profession that a few who have the management of this branch should be wedded blindly to a particular belief. However much our wishes may incline us to favour vaccination, we must not be like the advocates at the Old Bailey, determined to bring off our client victorious, whether deserving or not, because truth will have its sway at last, and it may be doubted whether the practitioners of the next century will not laugh at the manner in which we have been misled by Dr. Baron; even in his last report he first tries to con-

vince us that vaccination is much better than inoculation, and then turns round and argues that they are one and the same, as instanced by the late experiments of Mr. Ceely, which experiments he says have only confirmed the original belief of Jenner, that the two diseases are identical\*.

There is but one hospital in England, I believe, for the treatment exclusively of small-pox, and it seems that the report from that hospital during the late epidemic was not so favourable to the cause of vaccination as Dr. Baron wished it should be, and hence it is passed over by him nearly in silence; Dr. Baron, in fact, refusing to accept one of the largest masses of evidence to be found in any one place in England, on the subject he was professing to give the profession the best information he could. But this is not all, and I wish the point to be particularly remarked: the most laborious and accurate work published in Europe, on small-pox and vaccination, that by Dr. Heim, in Germany, and which accords, so far as I can understand, with the experience of the small-pox hospital in London, has also been passed over, in Dr. Baron's report, in the most cursory manner, although this work was published nearly 12 months ago; and since the formation of the vaccination section of the Provincial Medical and Surgical Association †.

Taking all these points into consideration, the errors actually committed, and the evident bias of Dr. Baron in favour of his cause, the profession must view with me the Report of the Association as giving any thing but a just and impartial account of the state of vaccination in England.

I have the honour to be, sir,

Your obedient servant,

SCRUTATOR.

Oct. 19, 1839.

## ON THE VENEREAL DISEASE.

*To the Editor of the Medical Gazette.*

SIR,

I SHOULD not, perhaps, have deemed it necessary either to the advocacy of sound chirurgical knowledge, on the one

\* Vide Report Vaccin. Section, pages 59 and 96.  
† Vide No. 13, British and Foreign Review.

hand, or to my own reputation, on the other, to have offered any remarks on the letter of Mr. Welbank on venereal diseases, published in the number of the *GAZETTE* for October 12, had I not myself experienced some difficulty in detecting both his meaning and the intent of its publication.

That small fragment of the professional public who ranged with me among the list of students and observers on venereal phenomena (to use a somewhat comprehensive term,) have read the letter of Mr. Welbank and the lectures to which it alludes, would feel inclined to the conclusion that that gentleman's comments were pointed against me, and my unheard-of opinions on venereal diseases. This, I confess, was my first but mistaken impression; and as few will undertake, as I have done, to investigate his meaning by repeated perusal, I suppose I must be under the imputation of a species of ingratitude, in promulgating doctrines at variance with the school in which I have already acknowledged I first derived both interest and instruction. Believing, as I do, that our views on this subject are almost identical, in relation to its general division, as well as to the more important consideration of treatment, there yet remains one point of difference between us, which I conceive to be of sufficient moment to warrant some notice.

My landmarks, I will take on myself to reassert, are clear and definite. I believe I have succeeded in simplifying and rendering easy of comprehension, at least to the class of students to whom my lectures were delivered, the variety of venereal disease they are required to know. Mr. Welbank conceives me in an error, in referring the great variety of venereal sores to one *primitive* origin, and assuming their complication of characters to be dependent on local and constitutional peculiarities in the affected party. If I find that the experience of Mr. Evans detected examples of different forms of disease appearing in three or more individuals who had had connexion at the same period with the same woman; if daily experience furnish examples of the repetition of the same form of disease in each person, one man's liability exhibiting itself in the form of *venerole*, a second of *gonorrhœa*, a third of *phagedæna*, these forming the largely predominant, though perhaps not the

universal characters of the diseases produced in the respective parties; and if, in addition to the above, I find venereal sores produced where venereal diseases did not exist; in other words, that venereal sores are occasionally of spontaneous origin;—I feel justified in deducing from these facts, for facts I believe them to be—that, however distinct and individualized may be the character of the disease when formed, the poison which produced it had not distinctive characters, from which may be inferred with certainty the nature of the product. This, at least, is my opinion—an opinion which I have not hastily adopted.

Mr. Welbank has concluded his letter by reference to the labours of Mr. Hunter on this interesting subject, claiming for him the gratitude of posterity. Who could venture to dispute his claim? Who could read his work on the Venereal Disease without offering his tribute to the patient and unprejudiced investigation, the dispassionate reasoning, and the simple but able description, which characterize it? In acknowledging, however, with all grace, the rich stores of information which he has furnished us, I only desire that justice be done to others, in acknowledging that the labours of Mr. Hunter have effected much, I only deny that he has done all; and I would ask Mr. Welbank, or any other member of our profession, well informed on venereal disease, whether were he content to rest on Mr. Hunter's work as the guide of his future practice, he would acquire such knowledge as would give him confidence in the management of one-third of the venereal diseases he is required to treat.

If Mr. Welbank's extensive opportunities have convinced him of the existence of a variety of venereal poisons, he himself could form the best comment on the competency of Mr. Hunter's book as a guide to treatment; for Mr. Hunter was acquainted with but one; yet, according to Mr. Welbank, he must have seen all. We reasonably infer that he knew but one, for he describes one only. The present existence of the Hunterian chancre is but a small item in the question. The most important and the most interesting of all questions is that of determining the forms of disease for the cure of which mercury is indispensable. And here it is that Mr. Car-

michael and the army surgeons have acquired a just and honourable renown. In the treatment of every variety of venereal disease Mr. Hunter had but one remedy, viz. mercury, the remedial influence of which formed with him a test of their genuineness. But a large proportion of venereal sores, including the common *venereola* of Evans, and the various forms of phagedenic sore, are notoriously curable without mercury. These are the diseases that greatly predominate in practice, both private and public; and to these I submit that the description of disease appropriated to Mr. Hunter does not apply.

Mr. Evans says that the *venereola* predominates in a proportion of nine-tenths of all venereal diseases, a statement which I do not imagine Mr. Welbank will dispute; yet the *venereola* is characterized by appearances in many respects diametrically opposed to those of the Hunterian chancre, being destitute of induration, and is perhaps still farther removed from it as regards the exigencies of treatment. But besides *venereola* we have phagedenic primary diseases, and non-venereal sores, leaving a proportion of about one-fiftieth of venereal sores to bear the stamp and impress of the true Hunterian chancre. Yet Mr. Hunter gave mercury in all, and says that primary induration is a common attendant symptom.

The laudation of Mr. Hunter's work on venereal disease appears to me an effort of especial grace on the part of Mr. Welbank, himself the author of a pamphlet on syphilis, which subject I presume he may have selected, as the only form of primary sore untouched by the masterly hand of Mr. Evans. But Mr. Hunter knew nothing about a "plurality of poisons," he speaks but of two primary forms of disease, the "gonorrhœa" and the "chancre." If a plurality of sores exists now, (and that it does I have no doubt,) it existed in all human probability half a century ago, viz. at the time of Mr. Hunter's labours. If Mr. Hunter's description be founded in nature, then were there in his day no "plurality of sores," for he describes but one; if, on the other hand, a plurality be established, then was his description so imperfect as greatly to detract from the merit of his work, which, notwithstanding the labour and care bestowed on it by its author, will not rank among

the foremost of those works which are destined to convey to posterity the splendour of his name.

I am, sir,  
Your obedient servant,  
FREDERIC C. SKEY.

14, Charter House Square.

### THE COMPLETED REGULATIONS FOR STUDENTS.

THE College of Surgeons having just issued the regulations by which all henceforth who wish to obtain their diploma must be content to abide, we are now enabled to afford our readers, in a brief sketch, an account of the demands for previous education which each of the four medical establishments of the metropolis makes upon the candidates for its honours or its privileges.

To be examined for the license of the Royal College of Physicians, a candidate must be twenty-six years old, and have studied medicine for five years; he must have attended medical practice for three years (of which one at least must have been passed in this country), in a hospital with not less than 100 beds; he must have attended lectures on anatomy, medicine, forensic medicine, chemistry, materia medica, botany, midwifery, and surgery; he must pass satisfactorily an examination in translating Latin (at least), and three others in writing and *vivâ voce* on anatomy, medicine, and therapeutics, which are held on three separate days. Practitioners 40 years old, or upwards, are examined on presenting satisfactory testimonials, without reference to their education.

No restriction is made of the schools or hospitals to be attended.

The license of the College of Physicians makes its possessor a Doctor, with liberty to practise whatever and wherever he pleases (provided he does not trench on the rights of apothecaries), and guarantees him the defence of the College against opponents unauthorized to practise, provided he himself practises in London, or within seven miles thereof.

A candidate for the license of the Apothecaries' Company must be 21 years old—have been apprenticed to an apothecary for five years, and have studied, by lectures and practice, for parts of three years; he must have attended lectures on anatomy (lectures and demonstrations), chemistry, materia medica, medicine, botany, forensic medicine, and midwifery; he must have dissected, studied practical chemistry, attended clinical lectures on medicine, and seen the medical practice of an hospital for eighteen months. His examinations are in translating a small portion of Latin, and in *vivâ voce* answering of questions on all the subjects which he presents certificates of having studied, and occasionally on some others.

His license confers on the successful candidate a right to practise as an apothecary in England and Wales, and guarantees him a defence against unlicensed opponents.

For the diploma of the College of Surgeons a candidate for examination must prove that he is twenty-one years old, and has studied his profession for at least four years. He must have attended lectures and demonstrations on anatomy for three seasons; lectures on surgery for two seasons; and on medicine, chemistry, materia medica, and midwifery, for one. He must have attended medical practice six months, and practical pharmacy six months, and surgical practice for three years (exclu-

sive of three months' vacation in each.) The only restrictions made on the schools or hospitals are, that they must be in the United Kingdom, that the latter must be recognised, and that the teachers of anatomy and surgery should have been themselves examined and approved by the College.

The examination of the College of Surgeons rarely extends beyond *vivâ voce* questions in anatomy and surgery, with practical demonstrations of the bones and some simple parts. Neither Latin, nor any other general acquirement, is demanded.

Candidates for the Doctor's degree at the London University must be 23 years old, and bachelors of medicine in this or some other recognized university. For this preliminary bachelor's degree, a candidate must have previously studied medicine for four years, of which one at least must have been passed in this country; he must have taken a degree in arts in this or some other university, or passed a matriculation examination in mathematics, history, classics, natural history, and natural philosophy; he must pass two examinations, one at the end of his second, and the other at the end of his fourth year of study; the first consisting of anatomy and physiology, chemistry, botany, and materia medica; the second of physiology, pathology, therapeutics, hygiene, surgery, medicine, midwifery, and forensic medicine, on six at least of which subjects he must have attended a course of lectures; he must have dissected altogether fifteen months; have attended to practical chemistry, pharmacy, and midwifery; have seen the surgical practice of a hospital for twelve months, and the medical practice for twelve months (each with clinical lectures), and after these, dispensary practice for six months. Each of the two examinations occupies six separate sittings, viz. four in each, by written papers, for three hours each, and two in

each by *vivâ voce* questions, of uncertain length.

At the University of London, for the doctor's degree, subsequently to receiving that of bachelor of medicine, a candidate must have attended two years' hospital medical practice, or have passed some proportionate time in the private practice of his profession. He must pass examinations in intellectual philosophy, logic, and moral philosophy, (unless he have previously taken a degree in arts), and in medicine, at two sittings for writing, of three hours each, and one for *vivâ voce* questions, for an unstated length of time. The diploma of the London University is only honorary.

Thus, in a few lines, we have the essence of the laws that it has cost years and years of toil to make; these are the several systems which four distinct bodies of professional gentlemen have invented to maintain the honour of their science, and to guard, as far as they may, the interests of the public. The history of the changes which have at last, and we sincerely hope, for a long time to come, settled into the schemes that we have briefly described, would be interesting enough, but too long to be condensed into our present space; it is contained in our past volumes.

The most remarkable change is that of the increased liberality of opinion (as far as we can judge by its expression) which now pervades all the authorities, with regard to the circumstances under which medicine may be efficiently taught. It is only a few years since metropolitan schools were deemed essential by all the boards who took upon themselves to superintend the medical education of students; now, no one of them adheres to such a restriction: the College of Surgeons, which stood out longest against the levelling, at last joins in the common cession of privilege (for to its examiners, who are for the

most part London teachers, the exclusion of others was a privilege which they might have retained with advantage to themselves) and unites in the common invitation to men of all parts of the kingdom—"only assure us that you have studied so long, and in this form—pass our examination—and you shall have our diploma, with whatever benefits it may afford you."

It is a remarkable fact, connected with the above regulations, that the College of Physicians is now the most open, and the London University the most exclusive of all the four institutions.

The parties to whom the present liberality of system is the most important, are the practitioners and pupils who reside in or near large provincial towns, containing hospitals or infirmaries recognized by the Boards of Examiners. Pupils may now complete their whole course of education at such schools, without incurring any of the inconvenience or expense of a prolonged residence in London. What effect this removal of instruction will ultimately have, it is difficult to foresee. It is very improbable that medicine will ever be taught so completely or so well in the provincial towns as in London; the attraction which various considerations afford to induce the best men to settle in London, will always operate as forcibly on medical practitioners as on the professors of any other science or art. And again, the competition that must ever exist in a metropolis capable of maintaining twenty medical schools will always insure greater exertion, and a more accomplished class of teachers, than those who will be found in provincial towns, in most of which there will be only one school.

But this matter needs no argument; if we look over the lists of teachers in the provincial schools, we do not commonly find well-known names, nor even those of the practitioners of most emi-

nence in the towns where such schools are. Indeed it is evident that the activity of a large provincial practice will always prevent its fortunate possessor from encumbering himself with the engagements of a lecturer.

The College of Surgeons has also recently been induced to adopt a farther important measure; the examination of every new teacher of anatomy and surgery. This plan is indeed the only guarantee they can have to prevent pupils from becoming practitioners with even a less share of knowledge than some already make shift with—for, as we have often shown, a dependence upon examinations alone will constantly be found erroneous. Even with this guard, however, it will be necessary to render the examination more strict in exactly the same proportion as the education is permitted to be more lax; and especially we hope that each succeeding year will find the examinations at all the Boards, more practical, and more close tests of that knowledge which may be demonstrated.

The four diplomatizing companies having now fairly started, and in a way in which they cannot but be competitors, it will be interesting to observe their several progress. Some years must probably pass before the public will appreciate their differences and relative advantages, or cease from habit to expect the majority of practitioners to be surgeons and apothecaries. But after that time has passed, it is, we think, quite uncertain what will be the favourite diploma. The apothecaries, if they retain their privileges, will have of course a large number of compelled licentiates, but between the three other corporations whose diplomas are all virtually little more than honorary, no foresight can determine the result. That the general result to the public will be beneficial there can be little doubt, but through whose medium the benefit

is chiefly to be dispensed, is a problem to the solution of which time alone can bring us.

---

## TWO CASES OF ARTIFICIAL ANUS FORMED IN THE LEFT LUMBAR REGION.

---

CASE 1. — Madame D., aged 48, of a nervous and sanguine temperament, had been subject to constipation for many years. She had stools with intervals of seven or eight days between them, and never without the previous use of clysters. They were often accompanied with sharp pains about the rectum, and more or less abundant discharges of blood. Sometimes there was sudden hemorrhage from the anus, without its having been preceded by any kind of effort.

The catamenia ceased about two years ago, and their disappearance was gradual.

About a year ago Madame D. consulted M. Amussat, who ascertained that there were polypous vegetations in the urethra, and excised them.

Madame D. always had the appearance of good health, and her functions were well performed, with the exception of the painful act of defecation. About the beginning of last May she was attacked with more obstinate constipation than ever, accompanied by sharp colic. It was in vain that clysters and baths were employed; it was in vain, too, that Dr. Barras administered the most powerful purgatives; nothing could overcome the retention of the fecal matter.

Under these circumstances, M. Amussat was called into consultation. He examined the rectum, with the intention of extracting the hardened fæces which might have accumulated there; but he soon found that the rectum was entirely empty. As he supposed that a crural hernia, on the right side, of old standing, contributed to keep up the symptoms, he tried to reduce it, and succeeded without difficulty. It was soon pushed down again, however, by the violent contractions of the abdominal muscles.

Mad. D. suffered from dreadful pain in the bowels, so that she uttered the most piercing cries, as if in the agonies of a difficult labour. There had been complete intercession of the alvine evacuations for twenty six days. The desire of going to stool was incessant. Ascending douches were thrown into the rectum, but this remedy failed, like the treatment hitherto employed; as also did galvanism. M.

Amussat, made anxious by the situation of the patient, in his turn requested a consultation, which took place on the 1st June, the practitioners present, besides himself, being MM. Barras, Fouquier, Breschier, Recamier, and Puyoo [by whom the cases are reported].

During the consultation M. Amussat again examined the rectum. He introduced his finger into the anus, at the back of the thighs, and carried it as high as he could into the rectum, an assistant pushing his elbow. In this way he ascertained that at the upper part of the rectum there was a hard and rounded tumor, not very moveable, and nearly twice the regular size of the neck of the uterus.

M. Amussat communicated to the other practitioners the result of his examination, and this result was specially confirmed by M. Recamier, who is well known to be gifted with a precision of touch that has often enabled him to form the most unexpected diagnosis.

The mechanical obstacle to the discharge of the feces being thus ascertained, nothing remained but to establish an artificial anus. The absolute necessity for this operation was unanimously acknowledged. It was evident that this was the patient's only chance of safety, and that the well-known maxim of Celsus was applicable, *Satius est enim anceps auxilium experiri quam nullum*. It was resolved, therefore, that the operation should be performed the next day. M. Amussat had already made his choice between the two modes of operating recommended by Littre and Callisen.

The former method has nothing but failures to show, except four or five cases carefully preserved in the annals of science; and yet it is the only one recommended in the schools. The second had hitherto been only theoretical, and was branded with general reprobation. M. Amussat had endeavoured to reinstate it in public opinion, in one of his papers on the disease of Broussais, because it seemed to him at once the most rational and the easiest method. He had consequently resolved to put it into execution when the opportunity offered; but however fixed might be his principles, it was necessary to convince his colleagues of the superiority of this method of operation.

Before the hour fixed for the operation, MM. Recamier and Breschet were present at the Hôtel-Dieu at the trials of the two methods in question, which M. Amussat performed before them on the dead body. These trials were discussed with all the interest called forth by the important case to which they were applicable. The result was, that the spot pointed out by Callisen was to be preferred, since the

danger of wounding the peritoneum was thus evidently avoided. The question, as discussed, suggested to M. Breschet the idea of exposing the colon, by following the method adopted by Abernethy in tying the external iliac.

Just before Madame D. was about to be operated upon, catheterism of the intestines was tried, as a last resource, with a pewter sound of large diameter, but without success. Moreover, the attempt had been previously made with an elastic gum sound to pass the part of the canal occupied by the tumor.

The patient was suffering under the following symptoms:—

There was nausea, with almost continual vomiting and hiccup. The abdomen was painful on pressure, and much swelled, and its circumference was almost doubled. There was constant return of cutting pains, accompanied by the most cruel illusions. The face was red, thirst great, speech short, anxiety extreme.

It is easy to see how imminent the danger was becoming.

Madame D. earnestly requested that the operation should be performed. She was placed on a bed somewhat raised, the anterior part of the body resting on cushions.

Those present were struck by the prominence formed by the accumulation of the feces in the left lumbar region.

A transverse incision, about four inches and a half in length, beginning at the external edge of the mass common to the sacro-lumbalis and the longissimus dorsi, was made in the left ilium, two fingers' breadth distant from the superior crest of the os ilium. The course of this incision comprised the thickness of the abdominal parietes, as well as the layer of cellular substance and fat in which the kidney is imbedded, and against which the posterior part of the lumbar colon reclines. This intestine being very much distended, showed itself, as it were, spontaneously between the lips of the wound. It was easy to recognize it by the disposition of its fibres and its violet tint.

Two slender arteries alone required torsion. A needle with waxed thread was passed across the most projecting part of the colon, to binder it from sinking and shrinking back when opened.

A trocar was then plunged into the intestine, and the canula immediately gave vent to gases, and to liquid fecal matter.

Lastly, a bistoury was directed along the canula, and the colon was cut into transversely for about an inch and a half, on which the feces suddenly burst forth.

Three large basins were filled with the product of this evacuation, which were more or less fluid, spouting forth almost

continually, and exhaling a very fetid smell.

Injections of tepid water were thrown along the intestine in both directions, and they brought away a considerable quantity of very consistent faeces, covered with thick mucus.

It will be easily conceived that this enterotomy was followed by prompt and well-marked relief. The congestive colour of the face immediately disappeared, and the abdomen gradually regained its ordinary size. When the abdomen seemed sufficiently relieved, the edges of the opening into the intestine were seized by means of three torsion forceps, and brought to the level of the external incision, as near as possible to the anterior angle of the latter.

Four stitches of the interrupted suture, two being on the superior margin of the incision, and two on the inferior, finally fixed the colon. A fifth stitch was applied between the opening into the intestine and the posterior commissure of the incision made in the skin.

M. Amussat occasionally pointed out that the stitches which he made with acupuncturation needles merely caused an almost imperceptible sensation of pricking.

The wound was covered with a small poultice, and a larger one was placed upon the abdomen.

No particular symptom appeared during the day, only a great prostration of strength was observed.

The night following the operation was passed quietly.

The next day, the 3rd of June, great sensibility began to be remarked in the right iliac region, and the circulation was quickened.

On the 4th, inflammatory symptoms appeared in the hernia already mentioned; no doubt, from its sharing in the general turgescence of the organs contained in the abdominal cavity. Redness, heat, and swelling, were perceived in it, and the signs of strangulation were threatened. There was a very acute nipping pain in the hernial tumor shooting towards the whole abdomen. Madame D. began to be much alarmed by the fear of having a new operation to undergo. The pulse was frequent and concentrated.

Leeches were applied to the inflamed part, and the patient was repeatedly placed in the hip-bath.

On the 5th, these formidable symptoms continued in all their severity. Cupping was thought necessary; and as the relief obtained by it was not sufficient, leeches were again applied.

On the 8th of June there was a marked amendment in the hernial inflammation; and from this day forward all the signs of strangulation gradually disappeared. The

crural tumor, which may be supposed to be caused by a portion of omentum, remained hard and indolent.

As to the wound, the day after the operation the mucous membrane of the colon formed a slight puffiness there, jutting two or three lines above the edges of the incision made in the integuments. The faeces were not at all stopped in their course by this puffiness, which only lasted three days.

The ligatures and threads used in the sutures came away about the sixth day. Agglutination had already begun between the edges of the wound and the intestines.

After having employed emollient lotions for a week, the part was sprinkled instead with wine and water in equal quantities, which cleared the surface of the wound without irritating it. Not the slightest erysipelatous blush was observed round the external incision, which went on rapidly to cicatrization, and closed entirely, with the exception of a rugous aperture corresponding to the intestine.

The faeces are figured, and are voided by the artificial anus; they are retained perfectly by means of a simple bandage fastened round the body, which Mad. D. loosens when necessary.

The somewhat premature expulsion of the faeces cannot injure nutrition, and the patient prevents their contracting the odour, *sui generis*, which they would obtain by a longer stay in the great intestine.

At present, four months after the operation, Madame D. is in the most satisfactory state of health: her appetite is good, and her complexion clear: she feels herself quite recompensed for the inconvenience of an artificial anus, by the recollection of the periodic tortures which she endured, and which often made her existence a burden.

Gases alone are now discharged by the natural anus.

Thus Madame D. owes her life to a surgical operation of great simplicity, which deserves to be rescued from the oblivion to which it had been condemned by theory.

In fact, Callisen's method, as we have already said, has the advantage over Littre's of avoiding any injury of the peritoneum. It is impossible to be wrecked on this shoal, particularly when operating on the living subject, while the intestine is distended by the stercoral tympanites, and the folds of the peritoneum are strongly put aside and back.

How is it that, in our best surgical works, and particularly in Dupuytren's article on anormal anus, a contrary opinion has been put forth?

In order to oppose Callisen's proposition, it has been urged that the skilful

surgeon of Copenhagen himself injured the peritoneum when trying the operation on the dead body; but it ought to have been added that Callisen having made a second incision more posteriorly than the first, no longer penetrated the cavity of the peritoneum. It is demonstrated that the peritoneum covers only the anterior part of the colon in the left lumbar region; but, in addition to the supposed danger of wounding this membrane, it has been alleged that the position of the colon is so uncertain, especially in children, that it might be difficult to find it, after having cut into the parietes of the abdomen. This objection has been repeated in every surgical work since Sabatier; but is far from being sound, as may be easily proved.

The colon in the left lumbar region occupies a determined situation, and is not floative, as has been asserted. This part of the intestine has not the mobility observed in the iliac colon, which is held in its place only by some very loose mesentery. This is an important distinction, as it answers one of the principal objections against Callisen's method.

M. Amussat, moreover, has introduced the following modifications:—

1. Instead of an incision parallel to the external margin of the quadratus, he makes a horizontal one, which renders it more easy to uncover the intestine, and carry it to the anterior angle of the incision.

2. The intestine is incised only in the posterior half of its circumference. This precaution will doubtlessly prevent the troublesome protrusion of the mucous membrane externally, and it will facilitate the cure of the artificial anus itself, when the obstacle which has opposed the expulsion of the feces has disappeared. This kind of obstacle comprehends various causes susceptible of being removed or combated, such as hardened and accumulated feces, polypi and other tumors, calculi, syphilitic vegetations, collections of different kinds in the pelvis, &c.

Thus art may hope to remedy the inconvenience which it has caused for the preservation of the patient; but, if we cannot hope to re-establish the natural course of the feces, their new mode of passage will have a favourable influence on the morbid growths existing in the sigmoid flexure of the colon or in the rectum. The vitality of the tunics of the intestines being diminished, the pathological alterations of a scirrhus character situated in them will go through their final transformations more slowly; and this slackening in their destructive progress will be another benefit derived from the artificial anus.

CASE II.—M. T. aged 62, and of a

feeble constitution, was habitually inconvenienced by constipation and piles. Defecation was accomplished with extreme difficulty, and the feces frequently accumulated in the rectum, so as to render it necessary to extract them. The stools were generally passed with blood.

For the last three years, in addition, the feces were mixed with purulent and ichorous mucus, and exhaled a very fetid odour. The different methods of treatment adopted for this serious affection, which seemed to be seated in the great intestine, were of no advantage.

M. T. consequently determined to come to Paris, about the 15th of May, 1839. His strength diminished every day, and he was extremely thin; and when the stools came away after the constipation, which was continually increasing in obstinacy, he felt excessively exhausted.

Dr. Foville being consulted, examined the rectum, where he ascertained that at the distance of two inches and a half from the sphincter there was a carcinomatous tumor, which had ulcerated, and which in some measure blocked up the intestine. This tumor was formed by a scirrhus prominence in the shape of an irregular ring studded with knots, into which it was difficult to introduce the end of the forefinger. On inserting a *porte-empreinte*, it was found that there was a stricture an inch and three-quarters in length. The obstacle which had stopped the course of the feces, and the real source of the morbid secretion, were now ascertained. The correctness of M. Foville's diagnosis was acknowledged in a consultation at which MM. Recamier, Amussat, Breschet, and Puyoo, were present. Different modes of treatment were proposed. Both dilatation and the use of a ligature were rejected. Excision was equally objected to, as it was feared that even a slight hæmorrhage might be fatal to a patient who was already so remarkably weak.

The method finally resolved upon was to crush the tumor, which was proposed and put into execution by M. Amussat, on the 30th of May. The operation was performed with long forceps which pinched and crushed the most prominent points of the cancerous tumor. The patient felt scarcely any pain. Nothing came away during the operation but a small quantity of blackish blood mixed with ichor. A sort of fleshy detritus was discharged at the same time by the anus. It was thought proper to keep up a continued stream of cold water in the rectum, in order to prevent the occurrence of inflammatory symptoms.

Some sloughs or fragments of atrophied membrane came away in consequence of the efforts made to detach them.

A week after this operation it was agreed that to complete its effects, cauterization would be necessary; M. Amussat canterized seven times, by means of a speculum and cylinders of caustic potash, with intervals of three or four days between each application, without any sign of inflammation appearing about the bladder or peritoneum.

Each time that the patient was cauterized, small refrigerating clysters were prescribed. Under the influence, either of the crushing or the cauterizations, which were applied from below upwards, and from within outwards, the tumor was reduced to little more than half its size. Meantime, M. T.'s general condition grew worse. The stools did not occur till after a lapse of ten or twelve days, and then with such violence as to lower the patient till he nearly fainted. His attenuation was extreme, and the skin on the sacrum was on the point of ulcerating. Hence, it was not thought prudent to continue the cauterizations, which must have been multiplied, in order to destroy by successive layers what still remained of the tumor.

M. T.'s symptoms were so extremely serious, that the only alternatives were to abandon him to a speedy death, or to adopt the only resource of the surgical art in such circumstances. The operation for artificial anus, which had lately been crowned with success, naturally suggested the thought of trying it on the present occasion. The double object might here be attained of remedying the retention of the fæces, and obviating their action upon the diseased rectum. On the 13th of July, there was a fresh consultation, at which Dr. Seguin was present in addition, and at which the necessity for the operation was unanimously resolved upon. It was performed by M. Amussat on the following day, according to the method he had already followed.

An incision four inches and a half in length, at the distance of four fingers' breadths from the spinous processes of the vertebræ, was made in the middle of the space comprised between the last false rib and the superior margin of the os ilium.

Towards the anterior angle of the wound a membranous projection was observed, formed by the peritoneum, and below which seemed to be the small intestines.

The colon in the left lumbar region was strongly drawn back upon itself, and was covered in a great measure by the quadratus muscle, whose fibres it was necessary to cut across. The intestine having been taken hold of with the necessary precautions, was incised in about the posterior half of its circumference. Nothing came out but gases and some small balls of fecal

matter. The colon was then drawn towards the anterior commissure of the incision made in the integuments, and fixed there by four stitches of the interrupted suture. Three stitches of the twisted suture were then passed through, to bring together the lips of the wound, but leave the intestinal aperture entirely free.

There was no general reaction, so to say. The feverishness under which the patient had continually suffered for a long time, particularly towards the evening, was scarcely increased during the three or four days which followed the operation.

In spite of the opening thus made in the digestive tube the fæces did not immediately change their course; watery injections thrown into the colon passed entirely by the natural anus. The anormal orifice did not give vent to the fæces till the 18th of July, and the evacuation was very copious. For some days the fæces continued to pursue their accustomed course, gases and liquids alone being discharged by the lumbar aperture. In order to dilate this orifice, it was necessary to employ, in succession, prepared sponge, elastic gum tubes, and at last wax bougies. These dilating substances facilitated the passage of the fæces by the artificial aperture.

To sum up, M. T. is evidently in better health than he was three months ago. He has been able to set off for his residence in the country. The hectic fever has disappeared; and the skin, which was yellow and of an earthy tint, is growing clear. All the functions have been re-established as well as so long and so great a deterioration of the system will permit. There is no longer any tympanitis, nor any forced stagnation of the fæces. The stools are regular, and figured fæces are expelled from the artificial orifice.

The tumor in the rectum has remained stationary; it has merely become harder, which must render it less capable of being irritated by the contact of the fæces, which may still continue to pass by the rectum, but which do so less and less every day.

Narcotic and chloruretted injections were indicated.

These operations speak in favour of Callisen's method as modified by M. Amussat. Shall we not be authorized in future to apply this method in cases of organic disease and insuperable stricture of the rectum? If it succeeded in the unfavourable circumstances under which it was performed, how many additional chances of success it will have, when surgeons have learned not to dread it, and when they have recourse to it before they have lost the moment for action by timid procrastination.—*Gazette Médicale*, Oct. 5th, 1839.

ON THE  
PRESERVATION OF SUBJECTS  
FOR ANATOMICAL PURPOSES.

BY

B. G. BABINGTON, M.D. & G. O. REES, M.D.

THE difficulty which has existed in supplying the Medical Schools of London with subjects for dissection has made it an object of much importance to discover a method by which human bodies may be preserved from putrefaction. This matter was more particularly brought to our notice last winter when great inconvenience was felt by the students, not only of Guy's Hospital, but of every school in London, from the insufficient supply of subjects for dissection.

There are, it is true, many methods now in use of preserving animal matter; and the processes of tanning, salting, pickling, drying, smoking, freezing, are so many familiar examples of those methods; but they are all more or less inapplicable to the purposes of anatomical science: thus, tanning, smoking, and salting, wholly alter the appearance and texture of parts; the corrosive action of acids is injurious to the instruments employed in dissection; and immersion in ice, which might possibly be practised, under favourable circumstances, in preserving whole subjects, would, independently of its expense and inconvenience, fail of its effect, when once the student had begun his work. The only antiseptic which is free from the foregoing objections is a solution of alcohol. This, it must be admitted, answers well for Museum preparations; but its powers are limited, and its injections into the blood-vessels, even in its most concentrated form, will not materially retard decomposition: moreover, it destroys colour; and when employed in sufficient quantity to admit of the immersion of parts, is too costly for common use.

Some simple experiments of a purely practical nature, which we were induced to institute in consequence of the foregoing considerations, have led to a discovery, the application of which promises to remove one great obstacle to the study of a most important branch of medical education. Our attention was first directed to those chemical substances which were known to coagulate the blood; and we accordingly prepared strong solutions of the following metallic salts; viz. sulphate of zinc, sulphate of iron, and diacetate of lead. We purposely stopped short of the point of saturation, from a belief that the greater density of the fluid, in the case of salts so soluble, would impede its flow on injection. Infusion of galls was also adopted,

from its powerful action in precipitating animal matters; and sugar in the form of syrup, being well known to possess preservative qualities, we thought it worth while to make trial of its capabilities. With each of these fluids a rabbit was injected, from the aorta; and another rabbit, killed at the same time as those which were made the subject of experiment, was kept, for the sake of comparison. They were all exposed to the air, in an open court; being merely protected from the weather by enclosure in a wicker basket, loosely covered with oil-cloth. At the end of three weeks, they had become putrid; and we could not perceive that, in any one instance, decomposition had been materially arrested. We were aware that arsenic and the bichloride of mercury both possessed considerable antiseptic powers. A solution of the former had indeed been tried with success at Guy's Hospital, in the previous year; but the poisonous qualities of these substances rendered them, in our opinion, as well in that of others more nearly interested in their employment, decidedly objectionable.

The total failure of our attempts had nearly discouraged us from proceeding further, when it occurred to us that the preservative powers which exist in certain hydrocarbonous fluids offered some probability that they might be turned to account in the prosecution of our object. Creosote and pyroxylic spirit more especially attracted our attention; and as the former was too expensive to admit of its having been advantageously used alone, we combined it with thrice its bulk of solution of gum-arabic. Two rabbits were injected; the one with pyroxylic spirit, the other with this mixture; and exposed to air, with protection from the weather, precisely in the same manner as was practised in the former experiments. At the end of two months, from the 30th of November, when the injection was performed, these rabbits were examined at Guy's Hospital, and declared, by all who saw them opened, to be as perfectly free from putridity, and as fit for all the purposes of dissection, as on the day when they were killed. It should be stated, that in these instances, as well as in the experiment with infusion of galls, a portion of fluid was injected *per anum*.

Having thus far perfectly succeeded, we resolved to obtain permission from the Hospital Authorities to make a direct experiment on the human subject, as soon as the weather became warm enough to test our method with sufficient severity. In the course of the spring, we were permitted to avail ourselves of the following opportunity.

On the 15th of May last, a convict at

Woolwich, 23 years of age, died of inflammation of the bowels; and on the 18th, his body was sent, by order of the Inspector of Anatomy, to Guy's Hospital, for dissection. It was neither cedematous, nor in a state of decomposition; and although the integument was somewhat fat, it was, upon the whole, in a fair condition for anatomical purposes. On the 21st, a gallon of pyroxylic spirit was injected into the aorta; and the body was placed in a water tight shell, or trough, made of slate, and loosely covered with a wooden lid. This trough was deposited in a cellar, the stone floor of which was about two feet below the surface of the ground. On the 29th the lid was removed, for the first time, and the body was found to be perfectly fresh. On this occasion, the flesh of the extremities was remarked to have become somewhat firmer than when the injection was first made. From the 29th of May to the 12th of June, the subject was examined, by removing the lid of the trough every two or three days; and no change was perceptible until the latter date. At that time the only sign of alteration was the appearance of two or three brown streaks—evidently veins—on the inside of the thighs; and a separation of the cuticle of the hands from the true skin, which began to assume a greenish hue. Every other part of the body was perfectly preserved, and of natural colour. There was no putrid odour on opening the lid of the trough, but the characteristic smell of the pyroxylic spirit was in some measure passing off. An incision into the middle of the right thigh, such as would be made in operating for popliteal aneurism, shewed that the fat, muscles, blood vessels, and nerves, were in a complete state of preservation. It should be observed, that ever since the injection of the subject the weather had been that of established summer; and that a second body received from Woolwich, was so decomposed in three days after its arrival as to be totally unfit for dissection. On the last examination, as well on two or three previous occasions, fluid was observed to occupy the bottom of the trough, and this it was thought advisable to remove: it was likewise determined to throw another quart of pyroxylic spirit into the aorta.

On the 24th of June, the body was removed to the dissecting-room, and placed on the table, for the purpose of being thoroughly dissected. With the exception of a greenish appearance on the outer part of the left thigh, and the brown streaks already mentioned, it appeared, when brought into the light, perfectly preserved. The skin on the back of the hands, instead of putrefying, had dried, and become transparent; while the greenness of

the left thigh proved, on incision, to be quite superficial. The dissection was undertaken by eight gentlemen, and completed by the 13th of July; and it is testified by them all that every anatomical purpose was as fully answered as if the subject had been quite recent. The various parts, on being laid open, were of natural colour and of firm texture. The tendons and ligaments were silvery and white, and the nerves had lost none of their tenacity. The pectoral muscles alone formed an exception to the natural colour which was elsewhere maintained: this appeared to be attributable to the macerating effects of a wetted cloth that had been laid upon the breast, to prevent evaporation through the aperture by which the injection had been accomplished. The parts which were exposed by dissection gradually dried; changing, in the course of a day or two, to a dark colour, and instead of putrifying becoming hard. The brain, although it had retained its form, was soft, and semiputrid, and unfit for demonstration: it must be borne in mind, however, that had the head been opened six days after death—at which period the subject was injected—this probably would have been the case. With the above exception, the viscera were all perfectly preserved: in proof of which, one of the kidneys, appearing, in colour and consistence, quite recent, was removed in the beginning of July, and after maceration in warm water, in the usual manner, was injected with wax. This experiment was made in order to ascertain whether the spirit produced thickening, or any other alteration, in the inner coat of the blood-vessels; which was found not to be the case, as the wax had fully penetrated the tissues of the organ.

Of the gentlemen engaged in the dissection of this subject, one complained that he at first suffered headache from the odour which it exhaled; and some, who were not so engaged, considered this to be more disagreeable than that of putridity. The same opinion is sometimes expressed with respect to the odour of parts that have been macerated in spirit of wine. Some allowance in favour of the pyroxylic spirit should be made on the score of novelty; and since its vapour is not poisonous nor injurious, any more than that of spirit of wine, it is to be presumed that the student would soon become accustomed and reconciled to it. In a first trial, upon the human subject, of the antiseptic powers of this fluid, a natural desire existed, on our parts, of watching its progress, and of noting such changes as might gradually occur. This led to the necessity of opening frequently the lid of the trough: and it has already been re-

marked, that this by no means accurately fitted the trough itself. The pyroxylic spirit being of a very volatile nature, it is obvious that its preservative qualities were much diminished by this proceeding. It is, therefore, not too much to expect that in an air tight vessel a subject thus prepared would not exhibit even those superficial changes which took place in this instance, and would be preserved for an indefinite period.

The advantages of employing pyroxylic spirit are, 1st, its extreme fluidity, in consequence of which it may be thrown into the minutest vessels. 2dly, its freedom from colour. 3dly, its cheapness; for a gallon is sufficient to inject a full sized subject: and even with the present limited manufacture of it, it is only half the price of alcohol; while it possesses infinitely greater antiseptic powers, and is, in common with that fluid, miscible with water, in all proportions. 4thly, its innocuous nature, and its freedom from any corrosive action upon steel instruments. We are not aware that there is any material disadvantage in its employment: the odour, it must be admitted, is more or less disagreeable to different individuals, but not so much so, to the generality of persons, as that of the putridity which it serves to prevent. Of this fluid, which must not be confounded with pyro-ligneous acid, or with pyro-acetic spirit, a full account may be found in the "Annals of Philosophy," N.S. viii. 69. That which we employed was procured from Morson's, in Southampton Row; and it may be had from any operative chemist\*.

NEW PROCESS  
FOR THE  
SEPARATION OF ARSENIC IN  
ORGANIC MIXTURES.

BY L. MALLE, M.D.

---

NUMEROUS experiments having convinced M. Malle that the ordinary processes (those of Hahneman, Rose, Fischer, Orfila, Rapp, and Taufflieb,) resorted to for the detection of arsenious acid in animal matters, are more or less ineffectual when the quantity of poison does not exceed one-tenth of a grain, he was led to investigate the subject closely, and now proposes the following method, as superior to those hitherto employed. The suspected matters, whatever be their nature, are to be placed in a porcelain capsule; any vegetable poison they may contain having been previously

dissolved with alcohol and ether; a solution of hydrosulphate of ammonia is then poured on them, in order to transform into sulphurets the arsenic acid, and any other metallic preparations capable of undergoing such transformation, which may chance to be contained in the mixture. The liquid is then slowly evaporated, and the residue treated with alcohol saturated with ammoniacal gas, in order to precipitate organic substances, and dissolve the sulphuret of arsenic. The contents of the capsule are next filtered, whereby a fluid, containing alcohol, ammonia, and the sulphuret in a state of solution, is obtained. The whole is next placed in a retort, communicating with a mattress, and then heated in a water-bath, so as to distil over the alcohol and volatilize the ammonia. The residue is then treated with nitric and a little hydrochloric acid, in order to destroy organic substances, and convert the sulphuret into arsenic acid and sulphuric acid. Once this is effected, nothing remains to be done but to separate the two acids by adding some ammonia and ammoniacal sulphate of magnesia to the liquid, which precipitates the arsenic acid in the form of an ammoniacal arsenite of magnesia. This precipitate is collected on filtering paper, and, after having been carefully washed, is reduced by exposure to a current of hydrogen gas, in a small tube, drawn to a fine point, as recommended first by Berzelius.

By this process M. Malle was enabled to obtain a metallic ring from half a pound of alimentary substances, to which five milligrammes\* of arsenious acid had been added; in order to remove all doubts of the nature of the metallic substance obtained, it was placed in a small vessel, full of dry oxygen, and thus converted into arsenious acid, which again was precipitated with hydrosulphuric acid in the form of a sulphuret, soluble in ammonia. —*L'Expérience*, No. lxxxii., and *British and Foreign Medical Review*.

CASE ILLUSTRATIVE OF THE ETIOLOGY  
OF  
SPONTANEOUS AMPUTATION OF  
THE LIMBS OF THE FÆTUS  
IN UTERO.

BY A. H. BUCHANAN, M. D.  
Of Columbia Tennessee.

---

IN the month of February last, I was called in haste to the country, about 3

---

\* *Guy's Hospital Reports*, Oct. 1839.

\* The milligramme is = .0154 English grain.

miles, to see a negro woman who was said to be suffering from severe pain in the back, and uterine hemorrhage. She was the mother of ten children, aged about 40 years, and had miscarried three or four times. On my arrival, I found she had aborted, and that the uterine hemorrhage had ceased. Upon an examination of the fœtus, which was between three and four months old, and perfectly formed, except a considerable flattening of the head laterally, I found the umbilical cord twisted about the thigh and neck in the following manner: the cord passes from the umbilicus under the right thigh, just above the knee joint, and continuing completely around it, passes under itself, and ascends in front of the chest to the right side of the neck, around which it twines twice, or rather twice and a half, so that two coils are seen in front of the neck, and three behind; it then passes in front of the left shoulder to the placenta. From the compressed appearance of the cord opposite the left shoulder, I think it passed under the left arm-pit to the placenta. Thus circumstanced, it is evident that any efforts made by the child to extend the thigh tightened the cord about the neck, and also about the thigh, as well as dragged upon its umbilical extremity, and obstructed the circulation. The same effects also are produced by extending back the head; but in this last action, the placental extremity of the cord is immediately pulled upon. It is very fair to conclude that the fœtus thus situated came to its death, either from the compression of its throat by the cord, or from its obstructed circulation, or from both, and the abortion was in consequence of its death. At many points where the cord twists upon itself, it is very much compressed, or rather atrophied. But the object of communicating this case is to call attention to the effects produced upon the thigh by the twisting of the cord around it. It may be seen by any present, that at the point of compression, only the integuments intervene between the cord and bone, all the other parts having disappeared; but the limb below the ligature appears as fully developed as its fellow, and the integuments immediately under the ligature appear sound. Now it is highly probable, had the child lived to its full time, the leg would have been amputated by the process of absorption carried on in consequence of the pressure of the cord around the limb, and that the opposite surfaces would have healed, as is usual in such cases, during the process of amputation; the limb below the ligature retaining its vitality by its connection with the integuments, they being the last parts to give way during the amputation; that

the leg below the knee-joint would have been more or less atrophied before its complete separation is almost certain.—*Minutes of the Med. Soc. Tennessee, May 1839; American Journal.*

### MEDICAL APPOINTMENT.

DR. ASHBURNER has been elected Physician-Accoucheur to Middlesex Hospital.

### APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, Oct. 24, 1839.

Charles Radclyffe Hall, Congleton.—Jukes Stirrop, Worcester.—John Turner, Macclesfield.—Alfred William Worder.—Joseph Wagner Hodson, Staines.—Charles James Freeman.—Edward Toze Woodward, Liverpool.—Samuel Crompton, Manchester.—Robert Nesbitt Robson, Durham.

### INFLAMMATION.

*Definition -- Nature -- External appearances --  
Condition of capillaries.*

GENTLEMEN,—In the following lectures it may seem to some persons that I have encumbered the subject by entering too much into detail. I have, however, not taken this course unadvisedly; I have not felt justified in stating positive opinions, without giving the inquiring and industrious student the facts upon which the opinions are founded. Those whose indolence renders them indifferent to such facts may rest content with the opinion, and not trouble themselves with the facts. I am happy to bear my testimony in favour of the general industry and inquisitiveness of the present race of medical students, and it is simply because I have ascertained that they are no longer content to receive from their teacher dogmatical opinions, but desire, however much they may respect those opinions, to be furnished with the materials for judging for themselves, that I have adopted this course; and my experience of every day leads me to the belief that it will not be unacceptable.

The term *inflammation* expresses the analogy which was believed to exist between the morbid phenomena which it designates, and those which occur during combustion. It is a metaphorical term, by which it was sought to define the state of any part of the body where redness, heat, pain, and swelling, are manifested, at the

same time that some change in the secretions of the part is brought about. Many attempts have been made to get rid of this term, and to substitute for it *irritation*, *hyperemia*, &c. We shall reserve the term, as conveying to our minds a morbid state characterized by increased vascularity, accompanied usually by an exaltation of sensibility, and always by a tendency to a secretion abnormal in quality or quantity.

The tendency of all observations accurately made in the present day is to establish an identity of the essential characters of inflammation, whether affecting one or another of the tissues of the animal economy. Convinced of this identity, and satisfied that the apparent differences are simply modifications dependent on structure, on idiosyncrasy, or other similar cause, I have determined, as a means of simplifying the comprehension of the condition, to consider only the essential characters, and to reserve those modifications until we come to consider the particular tissue or organ in which such modification is witnessed. In this way, bearing in mind the simpler characters, we shall have less difficulty in superadding one after another the modifications by which the phenomena are complicated.

Inflammation embraces an innumerable quantity of diseases—attacks all our tissues, all our organs, except the nails, the hair, the cuticle, and perhaps the articular cartilages—complicates the greater number of other diseases—develops the most singular phenomena, the most important sympathetic relations—presents the most varied terminations. Probably no remarkable morbid action occurs in the economy without inflammation; a solution of continuity, a wound, an ulcer, a contusion, a fistula, all require the presence of inflammation to remedy them. It is by determining inflammation that venereal and other virus appear to act upon the economy, either by exciting ul-

eration or developing tumors. It is often by means of inflammation that the system rids itself of morbid causes; it is often the crisis of fevers; it is by exciting it that art obtains the cure of many diseases; it probably excites the development of malignant products; and it is from the consequences of it that the greater number of the human race die.

Inflammation is a condition of any part of the living body usually characterized by redness, heat, pain, and swelling, and susceptible of passing into other states—the state of health, or restoration of the functions of the part—the state of exudation, of suppuration, and of gangrene; it may pass through one of these terminations, as they are called, or several of them at the same time; it may end in the development of another disease, or by death. This definition, which is only an abridged description, is very preferable to all those vague ideas, founded upon physiological hypotheses which were previously current. Still it is far from being rigorously applicable to all inflammations; difference of tissue, difference of seat, of idiosyncrasy, the acute or chronic varieties, occasion considerable modifications. There are many which present no sensible tumefaction; others which offer no redness, tumefaction, nor heat, either appreciable by the thermometer, or perceived by the patient; some which do not occasion during life any other symptoms than pain and fever; sometimes not even pain. The only phenomena common to all—the essential element, as it were—is the afflux of fluids to the part. Generally, however, the symptoms enumerated are sufficiently united to enable us to recognise inflammation. Clinical observation is usually sufficient for the diagnosis of *acute* inflammation, except there be extraordinary complications; but clinical observation is often powerless to detect cases of *chronic* inflammation, which are prepared, as it were, in silence, and insidiously undermine the constitution; it is then that pathological anatomy unveils the extraordinary alterations which have been brought about, inconceivable, yet compatible with life, to which the patient must have succumbed a thousand times had they been rapid. The disease is masked, perhaps, under an appearance of languor and debility; tonics are administered; the complaints of the patient are scarcely listened to; he might, possibly, have been saved by an opposite course. Pathological anatomy always establishes the existence of chronic inflammation—not always when acute.

Hunter attached the idea of inflammation to pain, swelling, redness, and heat, when these phenomena were presented as depending upon a direct or immediate cause,

and persisted for a certain time. He divided inflammation into five varieties or genera:—adhesive, which was subdivided into suppurative and ulcerative, cedematous, erysipelatous, gangrenous, and specific. Such were the principal divisions which Hunter admitted in inflammation; it is scarcely possible to say whether he considered them as varieties of the same phenomenon, which differed only in the parts affected, or were modified by temperament or determining cause—or whether he made them so many different entities. His ideas, so far as I can understand them, on the more prominent circumstances attendant upon this condition, I have collated and given in his own words. Thomson, who may be called the successor of Hunter, left to inflammation its four known characters—redness, heat, pain, and swelling. He rejected the distinction of causes into remote and proximate. He sought to distinguish the state of the blood vessels in inflammation. He found that vessels are developed, and that the course of the blood is sometimes accelerated, sometimes retarded in the inflamed parts. In that which concerns the local effects of inflammation, considered in its progress, its different periods, and the different tissues which it affects, he is very successful; then he follows the road marked out by Hunter—and he observes facts which are cognizable by the senses. Unquestionably he deserves to be consulted by those who are about to occupy themselves with an examination of the changes which supervene in inflamed parts—resolution, extravasation, suppuration, adhesion, ulceration, gangrene, the separation of eschars, and so on. I do not think that in all points he saw correctly, but I think he learned others to see better.

*Redness* is usually the first sign of inflammation; it varies from a slight rose to the deepest purple. The nature of the affected part has much influence upon its intensity and its shades; but the nature of the stimulus has perhaps a greater influence upon it. The red tint approaching to that of arterial blood is only observed when the inflammatory action is free; the purple or bluish tint is most commonly seen in inflammation produced by specific causes, and in this case it is sometimes of a coppery redness. As to the limits of redness, sometimes it gradually merges in the surrounding parts; sometimes terminates abruptly. It may be punctuated, striated, in patches, or arborescent. According to Hunter and Thomson the redness is always more decided at one point than others—from that point it gradually diminishes until it completely disappears. At first it is not decided; it is merely a slight rosy tint, like a blush upon the face.

At its commencement limited very much to the subcutaneous cellular tissue, it is only in proportion as the inflammation increases that the shades become deeper—in serous membranes this gradually increasing intensity can be easily followed. When the inflammation does not make very rapid progress, it passes through its stages with remarkable regularity, from a simple arborescence up to its diffusion in more or less extensive patches.

*Pain* is usually the first sign to which the patient's attention is directed, sometimes indeed it precedes redness, because it may be the direct exciting cause of it. It is also extremely variable in its character and in its intensity. A remarkable circumstance connected with it, is, that parts whose sensibility in the natural condition is inconsiderable, become when inflamed the seat of the most intense pain. It may be continued or intermittent—may suffer remissions or exacerbations of the most decided kind. In parenchymatous tissues it is usually dull and heavy, pungent in serous membranes, obscure in the mucous tissues, lancinating and pulsating in cellular structure, frequently only an inconvenient itching in the skin.

*Heat* is often very sensible to the patient, not always capable of affecting the barometer—is never superior in temperature to the blood at the heart: this is shewn by the experiments of Hunter. After exciting inflammation of the pleura in a dog, the peritoneum of a bitch, the rectum and the vagina of an ass, he discovered scarcely any elevation of temperature; but then it must be recollected that these are situations where the temperature is always high as compared with the surface of the body. On one occasion the thermometer inserted into the tunica vaginalis after the operation of hydrocele, indicated an increase of  $6\frac{1}{2}$  degrees. Scudamore states that he has observed a similar elevation in gouty joints. Goupil has found that in cases of phlegmonous inflammation there is an elevation of temperature at the surface amounting from one to five degrees: he also ascertained that, as soon as the presence of pus is indicated, the temperature of the part undergoes a very sensible decline. It must not, however, be understood, because our thermometrical experiments have been so undecided, that there is not almost always an increase of temperature produced at the part. It is possible that any excess of heat may be dissipated, by those means which the living body unquestionably possesses of maintaining a remarkable uniformity of temperature. Besides thermometrical evidence of increase of temperature, the skin in an inflamed part is hotter to the touch than the surrounding parts—inflammation communi-

cates to the part it affects a remarkable power of resisting cold: the ear of a rabbit inflamed by freezing could not be frozen anew (Hunter.) A phlegmon rapidly heats lotions applied to it—the patient experiences more heat if the skin be dry, and there be no evaporation.

*Swelling* presents as many varieties as the other signs—it varies with the intensity of the stimulus and with the texture of the affected part: the swelling of the testicle is a powerful illustration of this. In less than thirty hours this organ may acquire a bulk four, five, or even six times greater than is natural; the breast, the lymphatic ganglia, are also susceptible of enormous tumefaction. Usually in membranes the tumefaction is much less considerable, especially in the serous; they are often, however, apparently much thickened by the formation of false membranes. The tumefaction is sometimes circumscribed, at others diffused; its limits may be exactly traced or not.

Lobstein wished to establish four grades of inflammation which he termed *phlogosis*, *epiphlogosis*, *metaphlogosis*, *hyperphlogosis*. The first he restricted to that state in which the minute vessels were injected and apparent on a white ground. The second where the injection was more decided, the globules arriving even into the external vessels, accompanied by a lymph susceptible of coagulation, but without change of structure in the tissue. The third where the membrane was gorged, but without renitence or induration; the blood appearing not only to have distended the vessels, but even to have been extravasated into the cellular areola; the vascular ramifications being no longer discernible, the part resembling a red fleshy mass, blood may be exhaled on the surface. Chemosis gives a complete idea of this condition. The fourth where the tissue is greatly gorged, the resulting tumefaction being hard and renitent: if a mucous membrane be affected, the free surface is unequal and mamellated, cracked, excoriated, and suppurating; if a similar state affect the cellular or parenchymatous tissue it constitutes phlegmon which may end in abscess or gangrene. Though this division relates only to the form, he believed it justified by higher and more important considerations; that each had its proper character, its peculiar termination, and seems to have its predilection for particular tissues. *Phlogosis* attacks in preference the laminae of the cellular tissue and serous and mucous membrane: it may be very intense, determining very grave symptoms, according to the nature of the affected organ; it may occasion death in a short time. After death it may present arborescent injections, or only extremely fine vascular ramuscles,

like interrupted streaks; or may present a material product in the form of a fluid, sometimes serous, slightly yellow, diaphanous, and a little viscid; sometimes turbid, like soap-water or whey. *Epiphlogosis* affects the same parts as phlogosis; its product is constantly a plastic lymph, uniting together parts between which it is interposed. In consequence of this circumstance it has obtained the name of adhesive inflammation. It does not pass on to ulceration or gangrene, except in some instances. In many cases this state succeeds to phlogosis; this happens in the skin after the application of a blister. That action by which the vesicle is produced is phlogosis; that by which the fibrinous stratum is produced is epiphlogosis; the effusion in hydrocele is a consequence of phlogosis. We cure it by producing epiphlogosis. *Metaphlogosis* prefers the cellular tissue, the parenchyma of organs, and the skin; it may terminate by resolution, not by induration; it has a great tendency to gangrene. Rubeola, scarlatina, erysipelas, are specimens of it. *Hyperphlogosis* attacks in turn, or simultaneously, the common cellular tissue, that of the parenchyma of organs, mucous membrane, skin, periosteum; it alone passes to suppuration. Frequently the same organs are susceptible of being affected by many modes of inflammation which have nothing in common but the seat. Thus croup, laryngitis, and phthisis laryngea, attack the same part, each being different in its course, its symptoms, and its termination. Upon the skin we see rubeola, scarlatina, variola—why are they dissimilar? partly, perhaps, because they belong to distinct modes of inflammation.

That these distinctions may have been worth something to so close an observer, as Lobstein, is probable—that they are worth little to other men is more probable. If they occasionally have a separate existence it would be a difficult matter to make them out. Generally I will venture to say that they are merely a progress of a common inflammation—or an occasional consequence of a specific one, or of the particular state of the individual.

In penetrating further into the nature of inflammation, we must examine, first, the irritation which directs towards the point an increased quantity of blood (*ubi stimulus ibi flexus*;) second, the phenomena which occur in the inflamed organ; third, the alterations which are brought about in the blood itself. *Irritation* may be produced by many agents—by a stimulus directly applied upon the organ—a foreign body in the eye—cantharides applied to the skin—a thorn forced into the flesh. Besides these there are others more subtle; syphilitic, variolous, or other virus.

These stimuli give to the inflammation particular characters, and powerfully influence its symptoms, its course, its duration, and its termination. For instance, a person is exposed to cold; the perspiration which should have been eliminated by the cutaneous organ, is suddenly arrested; this matter returns into the circulating mass; it is separated anew by the action of secretion, and may be deposited on an irritable or sensible part, and inflammation may be excited there. If a specific virus such as that of variola, rubeola, scarlatina, acts upon the skin, the result will be different in each case. I admit that substantially the same change takes place as to congestion, alteration of the capillaries, and so on, but as to the vital changes we cannot deny that the operation is very different. It is not only by means of irritating agents from without that inflammation is excited, the humours of the system itself may undergo changes which may cause them to produce inflammation. Again, it may be excited by *continuity of organs*—be extended from one to the other; by *sympathies*. These depend sometimes upon nervous communications, sometimes upon the similitude of the organization, and so on. The sympathies of the first kind have long been known and admitted. The sympathies which depend on *similitude of organization* are those which are manifested when an irritation applied to one part is repeated in another whose structure is similar. Thus arsenic applied upon the mucous membrane of the vagina inflames it, and produces upon the mucous membrane of the stomach and intestines a similar inflammation; exactly as if the poison were swallowed. The sympathy through which inflammation of the testicle succeeds to inflammation of the parotid is inexplicable. Whatever be the mode of transmission of irritation, it is certainly the first phenomenon in the act of inflammation which should be pointed out, and if it be nothing else than the vital change which results from the perception of a stimulus, it follows that the nervous system is alone susceptible of being acted upon—of perceiving the action of a stimulus.

Though the causes of this condition are in kind infinitely varied, we may reduce them to two great classes—physical or chemical agents capable of including the irritating tissues of the body, their action being susceptible of demonstration; and vital agents, with whose immediate action we are less familiar. Some act rapidly; external violence, for instance; others slowly; high feeding, which gradually modifies the composition of the blood, impressing upon it new qualities, and causing it to become an irritant or excitant to our organs.

In what these changes of the blood consist it is not so easy to determine; chemistry lends us no assistance here; but a single inspection shews that it is richer in fibrin, and that it is covered with an inflammatory coat, termed *buff*. That this condition of the blood is irritating to the system, appears evident from the following experiment:—All the symptoms of impending inflammation are present; blood is taken from the arm, a certain quantity of fibrin is removed from the circulating mass, its place is to a certain extent supplied by diluent fluids absorbed from the mucous surface of the digestive system. This fluid thins the blood, its irritating qualities are rapidly diminished, the inflammatory symptoms subside, and a subsequent abstraction of blood yields no bull. In the one case and the other, the irritation, I apprehend, falls upon the nervous system of a part, or the whole of the body. By Bichat it was urged that the nervous influence has little to do with inflammation: he believed that the nerves have no influence on capillary circulation; that the organs, like the tongue, plentifully supplied with nerves, are rarely inflamed, whilst those which are almost insensible are more frequently affected. The answer to this objection is obvious—that if organs have no separate nervous cords, arteries which ramify in them are well provided; that though the circulation may continue in a paralysed limb, it soon loses much of its energy. That the irritation of a nerve does excite the circulation is shewn by the experiments of Sir E. Home, Krimer, and others: the former applied pure alkali upon an intercostal and pneumogastric nerve; the circulation was accelerated: the latter, after exciting inflammation in the web of a frog's foot, saw all the symptoms diminish, and the circulation completely arrested, the moment he cut the crural nerve. We shall now consider the evidence in support of the essential characters of inflammation.

"Inflammation," says Hunter, "has several well-marked peculiarities by which it may be distinguished." "I shall call by the name of inflammation whatever produces the following local effects: viz. pain, swelling, and redness, in a given time, and these dependent on, or the effects of, one immediate cause." "The act of inflammation would appear to be an action of the vessels; but whatever action it is, it takes place most probably in the smaller vessels, for it may be confined almost to a point where nothing but the smallest vessels exist. The larger vessels may be considered as only the conveyers of the materials for the smaller to act upon, and dispose of, according to the different intentions. However, inflammation

in a part is not only an action of the smaller vessels in the part itself, but in the larger vessels leading to it. This is proved by what occurs in a whitlow, where, although the inflammation be confined to the end of a finger, we can feel, when we grasp the finger, a strong pulsation in the two arteries leading to the inflamed part, while no such pulsation can be felt in the other fingers. This strong action often extends to or beyond the wrist." "Boerhaave's leading doctrine was, that inflammation consisted in an obstruction of the minute vessels, in consequence of too great a spissitude of the fluids. But I will venture to say that any cause which can obstruct the motion of the blood for a given time will become a cause of inflammation; for either the cause of the obstruction itself, or the blood being retained in the smaller vessels for a certain time, will either irritate or unite the parts, or, where it irritates, will throw the vessels into such actions as naturally arise out of an extraneous irritating cause, but not an increased motion of the blood behind to drive on the obstructed blood through the vessels, as has been supposed." "The very first act of the vessels, when the stimulus which excites inflammation is applied, is, I believe, exactly similar to a blush. It is, I believe, simply an increase or distention beyond their natural size." "Inflammation in most cases appears to begin at a point, for at the very first commencement all the local symptoms are within a very small compass, and they afterwards spread after the violence of the cause." "Parts inflamed, when compared with other parts not inflamed, show a considerable difference in the size of the vessels, and probably from this cause bring an increased number into view. I froze the ear of a rabbit, and thawed it again. This excited a considerable inflammation, an increased heat, and a considerable thickening of the part. The rabbit was killed; the head was injected, and the arteries of the inflamed side were found to be considerably larger than those of the other side." "As the vessels become larger, and the parts become more of the colour of the blood, it is to be supposed there is more blood in the part; and as the true inflammatory colour is scarlet, or that colour which the blood has when in the arteries, one would from hence conclude, either that the arteries were principally dilated, or at least, if the veins be equally distended, that the blood undergoes no change, in such inflammation, in its passage from the arteries into the veins, which I think is most probably the case; and this may arise from the quickness of its passage through those vessels." "The increase of temperature in

an injured part is real. A man had the operation for the radical cure of hydrocele performed at St. George's Hospital. When I opened the tunica vaginalis, and immediately introduced bulb of a thermometer, the mercury rose to 92. Next day, inflammation being developed, the thermometer being again introduced, mercury rose to 94½. Lord Hertford's servant was tapped the eighth time; fluid while flowing raised the mercury to 101; in twelve days afterwards it rose to 104." "What I would call oedematous inflammation is when the extravasated fluid is water. The extravasated fluid being principally the serum, renders the swelling more diffused than the inflammation itself." "From the connection between the living powers of the solids and fluids, we can hardly suppose that such an uncommon action could take place in the vascular system without producing its effects on the fluid; and therefore, from reasoning, we might suppose that the coagulating lymph undergoes some change in its passage through the inflamed vessels, which obliges it to coagulate more immediately or much sooner than it otherwise would." "If this lymph was no more than the coagulating lymph with its common properties, or the properties common to that which is circulating in the same vessel, it would in such cases only continue to throw in more coagulating lymph in addition to what was circulating; and therefore it would probably be carried on as a common mass." "From this should we infer that this coagulating matter is not simply the coagulating lymph, such as it is when circulating, but somewhat different from having undergone a change in its passage through the inflamed vessels." "In the adhesive inflammation, the vessels being enlarged, as before described, similar to what they are in the young subject, begin to separate from the mass some portion of the coagulating lymph, with some serum, and throw it out probably through the exhalant vessels, or perhaps open new ones." "If the divided parts are allowed to remain till the mouths of the divided vessels be entirely shut, inflammation will immediately follow, and will furnish the same materials for union which are contained in extravasated blood, by throwing out the coagulated lymph; so that union may still take place, though somewhat later, after the division of the parts." "Whether this coagulated lymph issues from the half closed mouths of the vessels which were cut, or from the surface of the opened cells, is not easily determined, but most probably it is from the latter." "In the extravasated matter I have seen a great number of spots of red blood in it, so that it looked mottled. How this red blood got there is

the thing to be considered, especially as a good deal was within the substance of the coagulum. Was it extravasated along with the coagulating lymph? In this case I should rather have supposed it would have been more diffused; and if not diffused, more attached to the intestine, and not in the centre of the coagulum. If it had been extravasated, one would have expected extravasation or injection; but we had none in any of these places. I have therefore suspected that the parts have the power of making vessels and red blood independent of circulation. This appears to be evidently the case with the chick in the egg." Such were the opinions of John Hunter on the more important phenomena of inflammation, and little change can be made in them in the present day. Our improved means of investigation have, however, enabled us to confirm them. Two hypotheses are generally upheld on the subject of inflammation—the one that capillary action is increased; the second, that it is diminished, as compared with the trunks from which they proceed. As in most cases of the kind, neither party is exclusively right nor exclusively wrong. The partisans of the first opinion bring together all the demonstrations they can collect in favour of the doctrine, that the vessels possess a power independent of the heart. Thomson enumerates at considerable length those facts which seem to support that independence—such as the redness of the cheek in blushing, the determination of blood to the head in strong intellectual efforts, arterial pulsations in certain hæmorrhages, the development of the uterine vessels in pregnancy, the beatings of arteries near inflamed parts, the jet from a punctured artery near an inflamed part, the good effects of debilitating topics, &c. But the essence of augmented action in a vessel being contraction, how can we conciliate it with the repletion and turgescence of inflamed parts? To get rid of this objection, recourse has been had to an active expansion or dilatation, which draws the blood with more or less force from all parts, even against its regular course. It is under this banner that we ranged Hunter, Bichat, Hildenbrand, Burns. The opposite doctrine, far from admitting in inflammation an increased action of the capillaries, only sees in the dilatation which they experience an index of feebleness. This theory is supported upon the results of microscopic observation, in which there is the most singular concordance as to the stagnation of blood in the capillaries: this all observers have witnessed when inflammation was established after its characteristic features. Induction had indeed in this respect preceded experiment; for Vacca, who wrote at Florence in 1765,

sustained, that in any period of inflammation the vessels presented no other condition than those of atony and relaxation. Winterl, in 1767, at Vienna, emitted similar opinions. Callisen, in 1788, repeated them, and refers to experiments of which he indicates neither the circumstances nor the author. Sehmlansky, in 1789, and about the same time, Lubbock, Allen, and others, maintained, more or less explicitly, that inflamed capillaries had lost all resistance, and were incapable of sustaining the impulse of the blood. Wilson Philip undertook the first positive experiments with the microscope, and gave a true sanction to those theoretical ideas: succeeding experimenters have confirmed them. Is it clear, however, that the dilatation of the arteries and the stagnation of the blood imply debility? Long dissertations have been framed to deny it, and to shew that the stagnation is simply the result of a convergence towards one focus, and a consequence of mechanical obstacles opposed to the onward progress of the molecules. However, so much remains demonstrated by experiment, that if the first effects of the action of a cause capable of producing inflammation is a manifest super excitation of capillary action, this super-excitation is only as it were preparatory to the decisive period in which the action of these vessels is suspended or there is a complete absence of reaction.

The first positive *microscopic* experiments on the subject of inflammation were those of Wilson Philip (1801). From his experiments on different classes of animals it resulted that the capillaries of an inflamed part are in a state of dilation and feebleness, whilst the larger vessels, whose state can be observed without the microscope, do not suffer an analogous dilation, but by the strength of their pulsations indicate a very evidently increased action. In the dilated capillaries the circulation is retarded; a little after, the same state is extended to the neighbouring capillaries. The course of the blood is enfeebled and arrested, and gangrene may supervene, unless the capillaries acquire new energy, by which their equilibrium with that of the larger vessels is restored. Many experiments, made with great care, by Thomson (1809), gave results analogous, in most respects, with those of Wilson Philip, but they did not allow him to admit so absolutely the retardation of the course of the blood in inflamed capillaries. Thus, muriate of soda applied upon the web of a frog's foot, gave, as a first result, the augmentation of velocity in the large and small arteries, and in the capillary vessels, upon which the substance was directly applied; the globules became less distinct, and the rapidity of their movement ren-

dered them less easy to follow than in the capillaries of an uninfamed part in the same animal: yet the reiterated or continued application of salt was always more or less speedily followed by a retarding or even a complete stagnation of the capillary circulation. The second general result of the action of salt was an apparent redoubling of the circulation in the arteries and veins, with a diminution of velocity in the capillaries. The third, and the most frequent result of the action of salt was a retardation of the circulation in the capillaries, the arteries, and the veins. From these and many other results he concluded that the circulation of blood, far from being always retarded in inflamed vessels, is, at the commencement of inflammation, frequently accelerated; that a retarding in the circulation in inflamed capillaries may occur at the commencement of inflammation, and last during its course; that this retarding is much more frequently observed during the progress than at the commencement of inflammation. Gruithuisen's microscopic observations, in supporting the doctrine of the primary dilatation of capillary vessels, furnished to that ingenious experimenter the opportunity of making curious observations upon the formation of accidental capillary vessels. To verify the results given by Wilson Philip and Thomson, and to conciliate the differences between them, Hastings undertook a series of experiments, which are detailed in his Inaugural Dissertation, and his treatise on Inflammation of the Mucous Membrane of the Lungs. In the first he relates the following observations:—After plunging the leg of a frog for a minute into hot water, the circulation was found to be accelerated, and the vessels slightly contracted; the experiment was repeated, and with the same results: a third time the limb was immersed, and a very decided dilatation was observed in all the vessels; the circulation was retarded, and the congestion was so great that the globules of blood, which were before very distinct, formed only a confused mass. After applying ice to the part the vessels were seen to contract, the globules of blood were moved anew, and soon the circulation acquired its natural character. The experiment many times repeated, and it being regarded as a fact, that stimuli applied directly upon the vessels, at first excites and afterwards enfeebles their action, Hastings proposed to resolve this question—Does inflammation occur during the period of excitation or that of debility? In eight groups of experiments which he has detailed, he applied different mechanical or chemical agents upon the webs of frogs' feet, and day by day he observed, with the microscope, the progress and the

termination of inflammation. His conclusions were, that certain stimuli, applied to a part, increase the velocity of the circulation and the contractions of the blood-vessels. During this state of excitation, the part is so far from presenting any thing like inflammation, that the caliber of the vessels is diminished, and the part itself is paler. But if the application of stimulus be long continued, the small vessels, which, in their natural state, admitted only a chain of globules, become so dilated as to receive a large quantity of blood, less fluid having lost its globular appearance, and passing much slower than natural, the part then appears inflamed. If the stimulus be very intense it frequently happens that the debility of the vessels, and the retarding of the circulation, seemed to be produced immediately, and without previous excitement. If we intermit the application of the stimulus, a certain time passes before the vessels recover their contractile power, and are able to resist the impetuosity with which the blood is propelled into them by the heart and great vessels. The application of a stimulus different from that which has excited the inflammation, sometimes brings about a resolution, dissipates it; in these cases the vessels contract, the blood becomes more fluid, presents globules of a paler colour, and floating in a lighter fluid; and at length it acquires the same velocity it had before the experiment. If, on the contrary, the disease persists, the blood stagnates, becomes darker and darker, and the vessels are much dilated. When this high degree of inflammation persists, gangrene supervenes; the part is then softened, yields to the pressure of the finger; the stagnant blood acquires a brownish yellow colour, and the dead point is separated from the living. During the cicatrization of the ulcer, resulting from the separation of the eschar, the adjoining capillaries are much distended by arterial blood, which moves very slowly. After the cure they resume their original dimensions, and the circulation its ordinary velocity. There are no new-formed vessels, except a solution of continuity has been affected at the part. In that case the divided vessels, very dilated and filled with red arterial blood, deposit a white matter upon the surface of the wound; and it is in the substance of this matter that the new capillaries are formed, which soon communicate freely with those at the edges of the wound. These new-formed vessels were known to Hunter, but this great man has certainly not described the mechanism of their development with the precision of Gruithuisen (1811). In the midst of the exuded matter, of which we have spoken, globules appear like so many red points,

which enlarge by little and little, take a stellated form, the rays of which come into contact, and coalesce with other similar rays. From this results a union of a certain number of stars, constituting an areola or net-work. In fact, in this way a new capillary net-work is formed, which communicates on all sides with already existing vessels. All these delicate researches, the object of which is to establish the changes which the capillaries experience in an inflamed part, have been completed by the experiments of Kaltenbrunner: the experiments of Thomson and Hastings he repeated, and discovered circumstances which had escaped them, and, from the results he obtained, he drew conclusions differing, in some respects, from theirs. He divided the phenomena he observed into three periods, of which the first may exist alone, or in combination with the latter—congestion, inflammation, fever. The first, characterized by an afflux of blood, distending the capillaries, arteries, and veins, to double or triple their natural size, by the rapid passage of the blood through the capillaries, thus preserving its arterial character; but the congestion is modified by the causes which produce it; the formation and absorption of lymph are interrupted; it may gradually decrease until the circulation is restored to its natural condition, or the phenomena may become more intense and inflammatory; the normal secretions are interrupted; absorption is more energetic. As soon as the circulation is accelerated by inflammation, the quality of the blood begins to undergo certain changes. The arterial blood-globule no longer changes into venous, in its passage through these vessels; passing so rapidly forward they even preserve their arterial characters after their arrival in the veins. If the inflammation increase still more, the coagulability of the blood is so far augmented that its globules appear glued together, forming a species of clot. These clots arrive in the arteries, pass along the capillaries, and get into the veins. When the blood begins to stagnate the globules unite into a homogeneous mass, in which all trace of their former conformation is lost. In fact, blood-globules he thinks cannot exist, except in motion, and lose their circular form as soon as they cease to move. He has shown how much the nature of the irritants may influence the effect, the alteration of the blood, the tension of the vessels, and the extent of the affection. Thus, *mechanical irritation* is applied; the globules of blood are frequently glued together; there is a persistence of their arterial qualities; but the affection is not extended. *Hot water* produces acceleration of the cir-

enulation, contraction of the vessels, abundant afflux of blood, globules enlarging and floating in a large quantity of serum, but the affection is more extended. *Dry heat* occasions acceleration of the circulation, and very remarkable contraction of the vessels, the globules are very red and frequently glued together; congestion is circumscribed; acceleration of the circulation is not very considerable; the globules are of a dark tint. He equally well observed and described the formation of stases. After a certain acceleration of the circulation, the movement is retarded, deranged, becomes uncertain; the blood seems to oscillate in its canals, then stops altogether and stagnates at different points. The stagnated points increase and trench upon the small veins, but rarely the small arteries. The stagnated blood does not entirely fill the vessels; it accumulates at some points, leaves others empty. He has also seen this stasis dissipated under a new stimulus, but often reappear, becoming larger than before. He has also shewn that the stimulus has its effect upon the colour of the blood. Muriate of soda gives the blood a deep purple colour, alcohol a bright tint, chloride of mercury a dull brown tint.

His mode of describing the formation of new vessels is unlike that of Gruithuisen: he states that when the circulation is accelerated the globules of blood are seen suddenly to escape from a capillary canal, fall into the surrounding parenchyma, make a way for themselves to pass along to another capillary canal; thus a new capillary canal is formed, the blood circulates in it; its formation is often the work of a few moments. The same phenomena are repeated at different points, and a rich net-work of new capillaries is thus formed, they inosculate with the old ones, dilate and assume the appearance of small arteries or veins, according as they are continuous with arteries or veins.

Prevost and Dumas showed that if we examine the capillary circulation in the web of the frog's foot, or in the bat's wing, we see the globules of blood moving in the vessels, and presenting themselves under different forms to the eye of the observer; and that the effects of inflammation may be thus studied, either with reference to the fluid traversing these vessels, or the action of the vessels themselves; but they did little more. Gendrin pursued his investigations at great length, and in the main with much exactness; he says, if a frog's web be placed in the field of a microscope, the red globules which circulate in the capillary vessels pass across the field in less than half a second. If the animal be agitated, their speed is increased, so that the passage may not ex-

ceed a third or a fourth of a second. If we irritate slightly with a needle the mesentery of a frog, the capillaries which before did not receive red blood readily admit them, and the coloured molecules traverse them as they do those of the web. In some seconds after the irritation ceases the quantity lessens, yet the capillaries, irritated by the contact of air, continue to admit the coloured parts of the blood. If we continue the irritation, either of the web or the mesentery, the blood flows towards the irritated point. The capillaries around this point are dilated, and seem to multiply, because the red fluid renders visible those which before were not seen. The globules arrive; their movement is retarded, and is at last suspended. The capillary circulation is then completely suspended at the irritated part, and for some distance around the retardation of the circulation and the dilatation of the capillaries are very evident. A little farther the circulation is more active; the still dilated capillaries and the globules of blood become more indistinct; at last, at the limits of the areola, the circulation is, on the contrary, accelerated, the capillaries dilated, and the blood richer in globules. All these changes are effected in four or five minutes. The same period of time is necessary for the cessation of these phenomena, if the irritation be continued no further, and the capillary circulation resumes its physiological state. If we produce irritation in the whole extent of a frog's web, by dipping in water at 70 degrees Reaumur, for four or five minutes, we observe a considerable acceleration in the capillary circulation, so that we can count under the microscope three passages in a second, and the globules are more numerous, and more in contact. This increased activity, occasioned by immersion in hot water, and the increase of diameter consequent upon it, diminish and entirely disappear within an hour. If we plunge the foot in boiling water, and leave it there a minute, the blood is immediately arrested in all the capillaries of the part which receive red blood; but in some seconds after the immersion we see numerous capillaries dilated and coloured, in which the circulation, much accelerated for some seconds, ends by becoming slower and soon completely arrested. When we cauterize with a heated stilette a point in the mesentery of a frog, the blood, which is arrested in the capillaries, dilated and injected around the eschar, is already in part decoloured at the end of ten or fifteen minutes. The greater tenuity of the vessels in this part than in others allows us to distinguish the phenomena of the decoloration of the blood in the gorged capillaries. The glo-

bules are seen to disembarass themselves of the small coloured vesicle which covers them; this vesicle remains adherent to some, and even partly covers them\*. At the end of two or three hours the whole mesentery seems converted into a tissue of vessels, in which globules are seen to move with great rapidity; but in the areola which surrounds the small eschar, the gorged vessels do not exhibit any movement in their cavity. Twenty hours after, the capillaries, gorged by a stagnant blood, are excessively numerous around the eschar; in some the blood is decoloured, and of a reddish yellow colour; in others it is quite red; the cutaneous tissue is become a little opaque and infiltrated. At the end of thirty hours there is an opaque appearance in all the inflamed tissue, which acquires a uniform reddish yellow colour; the focus of inflammation is extended. From the fiftieth to the fifty-fifth hour the capillaries begin to be decoloured; the fluid which fills them is yellowish red; they appear less dilated; the inflammation is circumscribed; and at the limits of the eschar a yellowish matter fills the capillaries. Towards the seventy-fifth hour the circulation is re-established in the gorged capillaries which limit the focus, but it is more rapid. There is so little distance between the globules, that they are with difficulty distinguished the one from the other. The eschar begins to be detached; the tissue which immediately surrounds it is opaque, and evidently softened; the principal gorged capillaries, which penetrate into its thickness, can be distinguished; some are of a greyish red, and dilated, without any appearance of circulation at their interior; others are of a greyish yellow, filled with a fluid of that colour, which moves very slowly, moving towards the eschar. This fluid presents globules of a greenish yellow, and others of a reddish colour. From the fourth to the fifth day the small eschar is detached; it leaves a solution of continuity, on the edges of which flexuous vessels, gorged by a greyish yellow decoloured fluid, are apparent. The tissue has become so opaque, that we can only distinguish these capillaries by the movement, slow, it is true, but incontestable of the globules in their cavities. At some distance from the little wound the circulation is entirely re-established, only it is still very slow. The sixth day the little solution of continuity is covered by a layer of a yellowish grey fluid, which appears to be without globules, and in the midst of which small

striae are seen, of a fluid substance, with rather voluminous globules. The fluid of these small lines does not appear to differ from that which is seen to pass slowly along the capillaries. The cicatrization is achieved towards the tenth day; then the circulation is re-established up to the limits of the wound; it is yet a little slow, but the vessels return to their natural size; the striae are no longer of a yellowish grey, "evidently purulent," it is a yellow, rosy, globular, half-coagulated substance; their motion is very slow. When the cicatrization is complete the circulation is re-established in the capillaries; they traverse the cicatrix very slowly, it is true, and they still carry some decoloured globules. We are now in a condition to inquire into, and to ascertain how those four signs—redness, heat, pain, and swelling, are produced, and what value we should attach to them.

## CLINICAL LECTURES ON OPHTHALMIA.

BY M. VELPEAU.

*Reported for this Journal, by*

J. HENRY BENNET, B.L. & B.S.

Sorbon.

---

*Non existence of arthritic, rheumatic, or scrofulous ophthalmia as a specific disease—  
Truly specific nature of syphilitic ophthalmia.*

*Arthritic Ophthalmia.*—As authors do not seem to care much about this form of specific ophthalmia, I shall only make a few brief remarks respecting it. I am myself perfectly convinced that what has been denominated arthritic ophthalmia by ophthalmologists is nothing else but iritis or choroiditis, or these two affections combined. My opinions on this subject are not formed *à priori*; they are the result of long-continued and attentive observation of disease. I have, it is true, sometimes seen the symptoms which are referred to this supposed specific form of inflammation in gouty patients, but I have much more frequently met with them in those who had never had that malady. Within the last three months, we have, as many of you well know, recognized these symptoms in at least twenty patients of all ages and of both sexes, and yet not one of them had ever been affected with gout, or even knew what the word meant. May we not also ask whether gout is a specific disease? This is a question which has not hitherto been satisfactorily

---

\* When we come to treat of suppuration, we shall state reasons for believing that pus-globules are not decoloured or transformed blood-globules.

answered, and yet the specific nature of gout ought certainly to be determined before we can rationally be called upon to recognize an arthritic form of ophthalmia.

The principal symptoms which are given as indicating arthritic ophthalmia are the following:—The vascularization, which is formed by vessels larger and more tortuous than in the other specific forms of inflammation, is separated from the cornea by a greyish or bluish ring or zone, about half a line in width. The sclerotica is of a deep blue or violet colour, the iris of a greyish or dirty yellow. This latter membrane appears as if had been macerating in some fluid; and the pupil, losing its regularity of form, becomes elliptical transversely. The pain is acute and resembles that of neuralgia.

On analyzing these symptoms you will find that they are merely those which I described when speaking of iritis, together with some others which are referred by authors to inflammation of the choroid membrane. The increased size of the injected vessels does not depend on a gouty diathesis, but on their having become slightly varicose, and is merely a consequence of the inflammation. The blue tinge of the sclerotica shews either that the choroid membrane is inflamed, or that the sclerotica being thinner than usual, its colour is slightly modified by that membrane. This we see frequently in children, in young people of a lymphatic habit of body, and in those who are affected with hydrophthalmia. Lastly, the changes which take place in the colour and in the form of the iris are symptoms of the inflammation of that membrane. I need not, I think, say any thing further on the subject; these considerations are quite sufficient to authorize our definitively setting aside arthritic ophthalmia.

The specific forms of ophthalmia which we have yet to examine, being those to which ophthalmologists attach the greatest importance, must be studied with care. Before, however, I enter into any details respecting the rheumatic and serofulous forms of ophthalmia, I have a few observations to make which are of some importance.

The existence of these two specific forms of ophthalmia cannot rationally be recognized unless it be first proved that serofula and rheumatism are really specific diseases. But has this been done? has science come to a definitive conclusion with regard to the nature of these affections? I do not myself believe that it has; I think, indeed, that their nature is still unknown, and that their history requires revising entirely. This, however, I cannot attempt for the present, as the details into which I should be obliged to enter would lead me too far

from the subject we are now discussing. I will merely observe that, in my opinion, serofula and rheumatism only differ from other diseases by the constitution of the patient, and by the nature of the tissue which is the seat of inflammation. Now, if I am correct, is it possible that they should always exercise such influence over inflammatory affections of the eye as to cause them to assume specific characters? To speak of the symptoms which are drawn from the vascularization only, how can we understand that the bloodvessels of the eye, the distribution of which is the same in every individual, should be injected in one manner in a serofulous subject, and in another in a rheumatic subject? I must confess I cannot see how there can be any difference. I am quite willing to allow that rheumatism or serofula, coexisting with an inflammatory affection of the eye, exercises more or less influence over that affection, as it would likewise over any other inflammatory disease; but I consider it absurd to assert, as it has been done, that a patient is rheumatic or serofulous merely because the ophthalmia by which he is attacked presents certain characters, although he himself may offer no symptom whatever of either one or the other of these affections.

#### *Rheumatic Ophthalmia.*

This is one of those forms of special ophthalmia which are the most frequently alluded to by ophthalmologists. M. Sichel, in the description he gives of "rheumatic ophthalmia," says that its principal seat is the sclerotica, aponeurotic expansion of the muscles of the eye, and that portion of the conjunctiva which covers the cornea. He also says that in some instances it attacks the membrane of the aqueous humour, and the serous layer which lines the anterior surface of the iris.

In the first stage of the malady the sclerotica becomes slightly vascularized, the conjunctiva remaining healthy. The vascularization of the sclerotica is formed by numerous small vessels which run parallel to one another, are perfectly straight, of a pale carmine colour, and, converging as they approach the cornea, terminate at about the distance of a line from that membrane. At a later period the redness becomes deeper, and the injected vessels extend so as to form a zone which occupies a considerable portion of the sclerotica. At the same time a second vascular layer becomes visible, constituted by more superficial and more voluminous vessels than the one we have just described; these vessels are moveable, follow a tortuous course, appear of a yellowish red colour, and evidently belong to the conjunctiva. These two vascular layers form round the

cornea a double injected zone, the appearance of which is often followed by chemosis. The dread of light and effusion of tears are very intense. At a still more advanced period of the disease the portion of the conjunctiva which lines the external edge of the cornea becomes covered superiorly and inferiorly with small red streaks. The free margin of the eyelids is also often sympathetically affected, and assumes a bluish red tinge. If the inflammation does not abate, it sometimes extends to the corneal conjunctiva, which then becomes more or less vascularized, and presents a milky white appearance; the vessels which give rise to the vascularization seem to communicate with those of the conjunctiva. When this is the case sight is always more or less impaired, indeed sometimes it is entirely lost.

Ophthalmologists also speak of a "rheumatic keratitis," which presents, they say, the following symptoms: the cornea does not become vascularized, but its transparency is nevertheless slightly impaired. Its external surface appears uneven, and is covered with small greyish specks. At a later period effusion of a whitish or bluish matter takes place in different regions, and the haziness being much increased vision, is nearly abolished.

Such are the symptoms which are supposed to characterize rheumatic ophthalmia. If, however, we examine them attentively, we find that in reality they are merely those which I described to you when treating of keratitis. We have now several patients in our wards affected with ophthalmia answering perfectly to this description; yet if you will take the trouble to question them you will not find one under the influence of a rheumatic affection. Indeed, I have repeatedly pointed out to you the fact, that the majority of both in-door and out-door patients whom we see presenting these symptoms, have never suffered from rheumatism. How can we, then, when cases of this nature are continually under our eyes, ascribe them to a specific affection, especially when we consider that simple inflammation of one or more of the membranes which enter into the formation of the eye satisfactorily accounts for their presence? It is a fact worthy of remark, that the ophthalmologists who adopt the opinions I am now opposing, do not describe a single form of inflammation, and that when they speak of traumatic inflammation they say it resembles rheumatic ophthalmia. Indeed it is evidently not on observation but on preconceived theoretical ideas that they have founded the ideal affection we are now examining. Rheumatism attacks fibrous tissues, and as in the eye we have a fibrous tissue, the scleroticæ, they have

made it the seat of a rheumatic form of inflammation.

The treatment recommended against "rheumatic ophthalmia," affords additional grounds for rejecting it as a disease. The remedies which we are advised to employ are principally those which are used as special agents in the treatment of rheumatism. Now let me ask those of you who have attentively observed the cases of diseases of the eye that we have lately had in our wards, whether they have seen me resort to such measures, when I have met with the group of symptoms that is said to indicate this special affection? They will be obliged to confess, that although I have only recourse to general remedies as adjuvants, or when indicated by the general state of the patient, the plan of treatment which I have adopted has generally been followed by the most advantageous results. On the other hand, does there exist a specific agent capable of curing rheumatism? Many authors say that there are substances, such as tartarized antimony, colchicum, extract of aconitum, &c. which exercise a special influence over this disease. I have very frequently tried them, but with very slight benefit to the patient. In rheumatic affections the usual treatment of inflammatory affections seems to succeed the best.

The few remarks which I have just made will, I think, suffice to shew you, that those who recognise this class of specific diseases of the eye are not only wrong in a scientific point of view, but that the ideas which they advocate have also a prejudicial effect on the treatment of ophthalmia, as they induce practitioners to resort to general measures against symptoms which would generally disappear under the influence of topical applications. I have frequently seen the inflammation subdued in a few days by the solution of the nitrate of silver, in cases which had been unsuccessfully treated by general remedies. To fully elucidate this question, it would be requisite to treat it at much greater length than I have done. I have, however, I hope, said enough to draw the attention of practitioners to the subject, and if I have succeeded in so doing I feel certain that my opinions will sooner or later predominate.

#### *Scrofulous Ophthalmia.*

A modern writer thus commences the chapter in which he treats of scrofulous ophthalmia:—"If there are persons to be found sufficiently sceptical to doubt that an inflammatory affection of the eye may undergo peculiar modifications attributable to the causes which have produced that affection, the arguments which scrofulous ophthalmia furnishes will surely

convince them of their error." To this I would answer, as I have repeatedly done, that no one doubts the influence which certain causes exercise over disease, nor do I mean in any way to deny it. My views may be expressed in a very few words; I do not believe that the symptoms of inflammatory diseases of the eyes are essentially modified in scrofulous subjects, or that the indications with regard to treatment are essentially different.

The arguments which the followers of the German school bring forward to support their opinions, are drawn, firstly, from the peculiar symptoms which they suppose scrofulous ophthalmia to present; and secondly, from the treatment which it requires. M Sichel recognises two forms of scrofulous ophthalmia: *scrofulous keratitis*. To these he also adds *scrofulous blepharitis*.

*Scrofulous conjunctivitis* is characterized by partial vascularization of that portion of the conjunctiva which is near the commissure of the eyelids. This vascularization is formed by streaks of a pale red colour, and represents a triangle, the base of which is turned towards the cornea, and the summit towards the internal or external canthus. Sometimes at the base of this triangle, papulæ or pustules of variable size are observed. The scleroticæ remains perfectly white underneath. There is neither photophobia nor epiphora.

Such are the symptoms which are usually attributed to scrofulous conjunctivitis. If, however, you will analyse them, you will perceive that they are exactly the same as those which I described to you in a former lecture as belonging to papular or partial conjunctivitis,—a disease which is met with as frequently on persons who are not scrofulous as on those who are. If any here still retain doubts on the subject, let them examine several patients now in our wards, and they will at once become convinced of the truth of what I now assert.

In *scrofulous keratitis*, although the cornea never becomes vascularized, it loses its transparency, and becomes cloudy. Effusion of plastic lymph may also take place in the tissue of the membrane, the surface of which then appears uneven, as if covered with sand, and assumes a greyish colour.

On consideration you will find that these symptoms, the most prominent among those which are attributed by authors to "scrofulous keratitis," belong in reality to the various forms of simple inflammation of the cornea, which I described to you a short time ago. You will, indeed, observe them quite as often in persons who do not present the slightest trace of a scrofulous constitution, as in those who are scrofulous—a fact, the correctness of

which I have frequently proved at the bedside of the patient.

The same remarks will also apply to *scrofulous blepharitis*, which is nothing more than the affection of the eyelids which I described to you under the name of glandular blepharitis.

But although I consider the symptoms which are generally supposed to characterize these specific affections as merely indicating simple inflammation of one or more of the membranes of the eye, I at the same time believe that the progress and duration of an inflammatory affection of the eyes is always more or less modified when it attacks a person whose constitution is deeply tainted with scrofula. In these instances the general state of the economy seems to impress on the ocular inflammation a kind of chronicity, so that effectually to subdue the disease and to prevent the relapses which are continually occurring, it is absolutely necessary to act on the constitution. But this alone does not certainly authorize our making specific affections of the ophthalmia which occur on scrofulous subjects. Does not, indeed, a general scrofulous taint exercise the same influence over the course and duration of all other diseases? How is it then that scrofulous ophthalmia has been so universally recognized, not only by ophthalmologists but also by the profession in general. This circumstance at first appears extraordinary, but it may easily be accounted for. Let us suppose that a practitioner meets with an ophthalmia, presenting the symptoms which I have enumerated in a scrofulous subject, and that shortly after he meets with several other scrofulous individuals, labouring under the same form of inflammation. Unless he examines the question as we are now examining it, he will probably feel perfectly warranted in establishing a scrofulous form of inflammation. When he has once come to the conclusion that such a disease really exists, his belief will not be staggered by meeting with cases which present the same symptoms, although there is nothing visibly scrofulous in the constitution of the patient. On the contrary, he will say that as his patient is affected with scrofulous ophthalmia, and no symptom of scrofula can be discovered, the scrofula must be in a latent state. A fact which proves at once the absurdity of such reasoning is, that this form of ophthalmia attacks persons of a sanguineous as often as those of a lymphatic constitution. I have, indeed, met with it in persons of every age, and of every temperament. Scrofulous individuals themselves are liable to be attacked by all the various forms of inflammation which I have de-

scribed, the symptoms varying according to the nature of the tissue which is inflamed.

In my opinion, even when no allusion is made to diseases of the eye, the word "serofulous" is very much abused, many persons being reputed serofulous although, in reality, they are perfectly free from such an affection. Indeed, in the present state of science, whenever a person has tumefied indurated glands in the neck, or underneath the lower maxilla, he is called "serofulous," although his flesh may be firm, his shoulders wide, his complexion highly coloured, and he has only become so from having received a scratch or some other trifling injury. It is really preposterous to call a strong robust person serofulous because he happens to have had an inflammatory affection of the lymphatic system. Properly speaking there is no such constitution as a serofulous constitution. When this expression is used we merely suppose that by it is meant a lymphatic constitution, in which the white fluids, predominating over the others, predispose to diseases of the lymphatic system.

In speaking of "rhenumatic ophthalmia" I told you that the belief in the specific nature of the disease was prejudicial in a therapeutic point of view; this may also be said with regard to serofulous ophthalmia. Thus, you will find that those who follow the ideas which I now oppose, consider general measures, and more especially those which are commonly employed in the treatment of serofula, as principally indicated, not only with really serofulous subjects, but also whenever the eye presents the characters which are supposed to belong to this form of inflammation. In my wars I have long followed, with great success, a very different plan of treatment. I treat the inflammation locally by the application of astringents, and have seldom recourse to general measures, unless the general state of the patient seems to demand it. When there is any constitutional predisposition, such as serofula—for I consider serofula to be nothing more than a constitutional predisposition—I always have recourse to those therapeutic agents which are calculated to modify it.

In fine, serofulous ophthalmia may be considered a nonentity that ought to be entirely rejected from nosological classifications, which it merely renders more complex without any practical utility.

From the remarks which I have made in this and in the preceding lecture, it is evident that ophthalmology would be much simplified were all these specific forms of ophthalmia definitively abandoned, and the inflammatory diseases of the eyes merely studied in the tissues which

are affected. That you may become convinced of the great advantage that would ensue, both to science and to therapeutics, I need only ask you to look into the works of the authors who have written on this branch of pathology; you will really be alarmed at the confusion—the chaos which reigns in them. In these lectures I have merely laid before you the doctrine of specific ophthalmia in its greatest simplicity, and yet you must have remarked that the lucidity which characterized the descriptions which I gave you of the inflammatory affections of the eye, considered apart from specific causes, disappeared as soon as we commenced the examination of the specific forms of inflammation. What, then, would it be were I to attempt to describe their various combinations;—were I, for instance, to speak of *rheumatico-serofulous*, *catarro-serofulous*, *catarro-rheumatic ophthalmia*, &c. &c.!!

In conclusion, I must again give it as my decided opinion, that all these appellations have no practical utility, and that, as they only tend to render still more intricate a branch of pathology which, from the structure of the affected organ, is inevitably of a very complex nature, I think they ought to be altogether abandoned. If the profession in general were to adopt these views, and to treat inflammatory affections of the eyes as simple inflammations of the tissues which enter into the formation of that organ, taking into consideration, at the same time, the constitution of the patient, ophthalmology would then be reduced to its most simple expression.

#### *Syphilitic Ophthalmia.*

An attentive and careful examination of the inflammatory diseases by which the eye is attacked, has shewn us that those forms of ophthalmia which authors have denominated *catarrhal*, *arthritic*, *rheumatic*, and *serofulous*, do not present anything specific either in their symptoms or in their treatment; but this is no longer true with regard to syphilitic ophthalmia, for it is an undeniable fact that syphilis does impress on inflammatory affections of the eye peculiar characters which require a specific treatment. When, indeed, we consider, that if, in pathology, there is a specific disease, it is certainly syphilis, and that, when the economy is deeply impregnated with the syphilitic virus, all other diseases which may occur appear to be more or less modified by that virus, we cannot but acknowledge that it is perfectly rational to admit the existence of syphilitic ophthalmia.

This really specific class of inflammatory affections must not be confounded

with the malady which I described under the name of "gonorrhoeal conjunctivitis." There is the same difference between these diseases as between a venereal chancre and a gonorrhoeal affection.

Some authors (M. Siehel among others) think that the iris alone is the seat of the syphilitic ophthalmia, but this is an error. The iris is oftener affected, it is true, than any other part of the eye, but the malady is also occasionally seen in other tissues. I have myself met with several cases in which the eyelids or the cornea were apparently attacked by this form of inflammation. A short time ago I had under my care a youth evidently labouring under syphilitic blepharitis. The margin of the eyelids was swollen, and presented a yellow copper-coloured appearance, the conjunctiva and the cornea being at the same time perfectly healthy. Every kind of treatment had been tried during a space of six months, but without success. Suspecting the nature of the affection, I submitted him to a course of mercury, and in a short time he was completely cured.

I have also seen cases of keratitis, in which the cornea was vascularized, and offered a peculiar copper-coloured appearance, and which had resisted every other plan of treatment, give way rapidly as soon as mercury was resorted to.

The symptoms which are given by ophthalmologists as indicating the presence of syphilitic iritis, are the following:—The iris presents a copper-coloured appearance, its tissue becomes turgid, and its anterior surface assumes a velvety aspect. At the same time the pupil, losing its regularity of shape, becomes deformed superficially and internally.

But this description is only partially correct, as the change which takes place in the form of the iris is merely a symptom of the inflammation of that membrane, and is not oftener observed internally than externally, superiorly than inferiorly. Indeed, as I have already told you, the modifications which may occur in the form of the pupil are not of the slightest avail towards distinguishing the different forms of iritis.

Soon small flakes, described by Beer under the name of *condyloma*, and by Müller under that of *crista galli*, make their appearance at the circumference of the pupil, forming, as it were, a kind of fringe. In addition to these symptoms, which may be considered characteristic of syphilitic iritis, when the inflammation is acute, there are others which generally accompany simple iritis, such as haziness of the aqueous humours, vascularization of the conjunctiva and sclerótica, and disorder of the visual functions. The pain

which the patients feel is generally greater during the night than during the day.

Whenever these symptoms are present, and the patient is or has been under the influence of syphilis, we may conclude that the inflammation is of a syphilitic nature. Syphilitic iritis may be classed among secondary syphilitic affections, as it is produced by the same cause and follows the same course.

Once we have recognized the syphilitic nature of this form of ophthalmia, it becomes evident that recourse must be had to an antisiphilitic treatment. If, however, the inflammatory symptoms run high before we resort to the specific treatment of syphilis, the inflammation must be subdued by general and local blood-letting, and by the other measures which I enumerated when speaking of acute iritis. If, on the contrary, the inflammation is chronic, we may begin at once the mercurial treatment. I generally order mercurial frictions to be practised on the internal parts of the thighs, and give internally the proto ioduret of mercury.

## ON SYPHILIS.

By HERBERT MAYO, F.R.S.

Senior Surgeon to Middlesex Hospital.

[Continued from page 195.]

[For the London Medical Gazette.]

*Description of chancre—Indurated chancre—Chancre without marked induration—Unindurated sores described by Carmichael—Venerola vulgaris of Evans—Opinion of Mr. Welbank—M. Ricord's account of inoculated chancre—Bearing of his experiments on the contagiousness of secondary syphilis, and the identity of venereal poisons—Practical diagnosis of chancre.*

CHANCRE may be described as a sore more or less circular, beginning by a small vesicle or pustule when the epidermis is entire, otherwise as a small ulcer, having a tendency to very slow increase, and to preserve one character, its surface being without granulations, the edge clearly defined, and the base and edge being either very much indurated, or only firm to the touch, which is more common, the firmness even in some cases being evanescent. The principal varieties of appearance which chancre assumes I shall describe under the

heads of indurated chancre, and chancre without marked induration. The criterion of chancre, which I recognize, is its liability to be followed by scaly eruption of the skin.

### I. INDURATED CHANCRE.

Mr. Hunter has described the indurated chancre in these words:—"The sore is somewhat of a circular form, excavated, without granulations, with matter adhering to the surface, and with a thickened edge and base. The hardness and thickening are very circumscribed; not diffusing themselves gradually and imperceptibly into the surrounding parts, but terminating abruptly." Venereal ulcers, exactly answering this description, are met with upon the corona glandis, and on the inner and outer preputium. The hardness approaches that of cartilage, so that the ulcer, at an early period, feels like a little cup of cartilage set in the flesh: sometimes the extent of the surrounding induration is disproportionate to the size of the ulcer, which has the appearance of a small hole in a nodule of condensed texture. The little ulcer on the nodule of cartilage sometimes closes, or skins over after a few days. It remains, indeed, liable to ulcerate anew; but if this does not happen, the permanence of the nodule alone may be considered evidence of local primary venereal action. The nodule left by an indurated chancre is sometimes considerable enough to form a prominent lump. One that was of the bigness of a pea, I was requested, some years ago, by the patient, a medical student, to cut out: he said that he had taken mercury a few weeks before, and that this lump had remained where the sore had been: I cut it out, and the wound closed healthily: in a short time he was attacked with siphilitic psoriasis.

It occasionally happens that the abrupt boundary of the induration, on which Hunter laid stress, is masked by common inflammatory condensation of the surrounding parts. In one of the most obstinate cases of chancre which I remember, the ulcer, which was an excavation that would hold a pea, was situated at the edge of the glans, and the surrounding texture, both of the body of the penis and the glans, was condensed to the extent of half an inch, beyond which the hardness gradually ter-

minated. The cellular texture of the prepuce renders it easily susceptible of this kind of diffused hardening, which, like the defined sort, sometimes assumes the form of a blind chancre. It is thus described by Mr. Babington:—"It is not uncommon that a primary venereal sore should assume the following characters:—A portion of the prepuce, of about the size of a silver penny, shall become slightly thickened, so as to lose its natural flexibility; and perhaps the surface shall be slightly excoriated. In the course of a few days, if the part is kept very clean, the excoriation, shall in many instances disappear, but the hardness shall progressively increase, assuming a more defined character, and at last forming a large flat mass of the size of half-a-crown, so inflexible and rigid that the prepuce cannot be everted without difficulty. There shall be no tenderness, no inflammation, sometimes no ulceration, at all; at other times only a slight dark-coloured excoriation of the surface."

The extent to which it is possible that the characteristic induration attending chancre may reach, when the cellular texture of the prepuce is invaded by it and lends itself to it, is well exemplified in the case of Evan Pugh, aged 60, reported in a clinical lecture by Mr. Lawrence. In this patient "the integuments of the penis and the prepuce were inflamed and swollen, and the latter could not be drawn back, although its orifice was not much contracted. There was copious puriform discharge. Just within the prepuce, at its lower part, two ulcerated prominences could be seen: these prominences, each of which was as large as the end of the thumb, were at first supposed to be the end of the glans in a state of ulceration." The glans, however, was found, on a more careful examination, to be behind these prominences, which proved to be an enormous induration surrounding a single ulcer. The ulcer healed, and the prominences disappeared under a course of mercury.

Mr. Carmichael observes that "chancre, when situated on the body of the penis, is of a dark livid colour; the ulcer is not excavated, but is on a level with the surrounding parts. It is attended with less induration than the excavated chancre; and is, in general, from the size of a sixpence to that of

half-a-crown; and even, sometimes, it extends round the body of the penis. Its edges are a little raised, and the surrounding induration very perceptible to the touch, although not in so great a degree as in the chancre described by Hunter. The livid surface is alternated every third or fourth day with that of a light brown or tawny colour."

Indurated chancre is seldom seen to attain any great magnitude: its extreme limits are commonly between a third and half an inch in diameter. This, however, it may be presumed, depends not more upon its sluggishness than upon its early subjection to treatment. Mr. Carmichael describes a chancre, the size of half-a-crown, situated on the external prepuce. I have seen an indurated chancre, of the same size, situated on the inner surface of the external labium. The patient, who was a respectable married woman, had known there was a sore on the part for six weeks. Not at first suspecting its source, I ordered anodyne poultices and a mercurial wash alone. Soon after this the patient fell ill of bronchitis, on recovering from which, after a protracted illness, I learnt that the sore was better, but of considerable size still. In four months altogether from the first appearance of the sore, she was attacked with siphilitic psoriasis of the throat, upon which she took mercury and recovered. About the same time, to clear away all ambiguity from the case, her husband became my patient, with siphilitic disease in the ulcerative form.

## II. CHANCRE WITHOUT MARKED INDURATION.

Chancres, attended with little or no induration, exhibit the following varieties:—They may be flat, or nearly so, and but little sunk below the level of the surrounding skin; or they may be sensibly cupped or excavated. After a time they are liable to become raised or elevated. These differences are principally attributable to difference of stage. An ulcer, at its commencement, if small, is necessarily excavated; as it enlarges, supposing its character to remain unaltered, it may become level; after a time it may throw up a fungous growth of organized lymph. Situation has something to do in maintaining the cupped figure of an ulcer, and local peculiarity of structure may tend to the same result.

Chancres belonging to this class, oc-

curing upon the inner preputium, are commonly flat, or nearly so. The surface, flat or slightly dished, and sunk but little below the surrounding skin, is of a reddish gray colour, and is uneven, from numerous little excavations in it. The border is raised but slightly; sometimes it has a narrow flat rim; sometimes it presents a sharp edge that is turned upwards, but not everted: in the latter case, the edge has often a remarkable semi-transparency. Sometimes there is a thin line of bright red immediately surrounding the edge of the ulcer; but this, like the last appearance, indeed, is only seen in parts where the epidermis is thin. The surface of the ulcer and its border have sometimes only firmness enough that their existence and form may be just distinguished by the touch: more commonly, though not approaching the cartilaginous induration of the first class, they have yet a positive firmness.

Such a chancre occurring on the outside of the prepuce, or on the body of the penis, is often, for a time, covered with a scab or crust of dried pus: if seen on the pustule breaking, its surface would have been slightly sunk, but flat, covered with a layer of ash-coloured secretion.

A chancre of the present class, when occurring in the furrow surrounding the corona glandis, or in the fossa of the frænum, remains longer excavated; when, containing a soft pellet of whitish secretion, it appears to have suggested to Mr. Bacot the term aphthous ulcer. As this ulcer enlarges, it becomes shallower. When beginning in the fossa of the frænum it commonly tunnels through below the frænum, which it afterwards divides; the shape of the ulcer then becomes irregular. When it occurs, again, at the angle of reflection of the inner prepuce, it appears to have a depth that does not really belong to it: it is formed of a circle, with a hinge at one of the diameters. If there is œdematous swelling of the prepuce, such a sore appears very deep, and being liable to be covered with dark coloured secretion, it may be mistaken for the commencement of burrowing phagedænic ulcer.

This kind of sore, when it occurs upon the glans, is cupped, the surface of the cup yellow, a zone of red margining its edge.

When an ulcer of the present class has existed some time, it occasionally,

like other ulcers that are unprogressive and yet not healing, becomes covered with fungous granulations, that are raised above the level of the surrounding skin. The raised surface is flat and smooth, and of a greyish-red colour, that is to say, not highly vascular: it is not indurated, but it has firmness enough to prevent its being crushed by slight pressure. Such a raised ulcer is liable to skin over in this state, when it remains a dry flat nodule, of the same degree of firmness as the ulcer which preceded it, and to which state it is liable to return.

Chancre upon mucous surfaces, in the male urethra, or in the vagina, internal to and free of the cutaneous texture of the labium, are commonly attended with very little hardening or inflammatory firmness. In the male urethra they may be occasionally seen presenting this character, when their circle all but reaches the orifice. When occurring lower down their existence can be determined only by the local tenderness. Sometimes, however, there is considerable induration round them. In the vagina, within the outer labium, and from thence to the cervix uteri, chancres are found that are small, and without induration, that are remarkably indolent in their progress, and slow in affecting the constitution of the patient herself.

I have thought it better to give the preceding account of certain varieties of sores unattended with marked induration, which I believe to be truly syphilitic, before adverting to the descriptions (as I conclude) of varieties of the same sores as given by Mr. Carmichael, and by Mr. Evans, and to the different views entertained by those writers respecting their varieties. I have the less hesitation in supposing that Mr. Carmichael's descriptions, of which I have immediately to speak, include the sores specified, that Mr. Evans appears to me to express the same opinion.

Mr. Carmichael describes, under the title *superficial ulcer without induration, but with elevated edges*, a sore of which to those, its principal characteristics, may be added, "that it sometimes displays a whitish, and at others a brown surface, without any appearance of granulations. It is not excavated, but is either on a level with the surrounding skin, or considerably raised above it; yet it is necessary to observe, that it sometimes seems indurated to the eye, and the ele-

vated edges of this ulcer give it the appearance of excavation. At its commencement it appears in the form of a small pustule, attended with itchings of the part."

Under the title of *ulcer, destitute not only of induration, but of elevated edges*, Mr. Carmichael describes a sore "raised above the surrounding skin, that exhibits a smooth surface, the colour of a healthy sore, but without granulations, and has somewhat a fungous appearance. Sometimes it is in a line with the surrounding surface, and *seldom is excavated*. These ulcers, which are far more general than any other to which the parts of generation are liable, vary from the size of a pea to that of half-a-crown, and are more frequently found on the glans and internal surface of the prepuce than elsewhere."

Now the first of these sores Mr. Carmichael has never seen followed by constitutional symptoms, and the latter he views as leading, in common with virulent gonorrhœa, to papular eruptions and other features of constitutional affection, perfectly distinguishable from the consequences of indurated chancre.

It is difficult satisfactorily to place these two kinds, described by Mr. Carmichael; but of the first, it strikes me that it is made to comprehend dissimilar cases. Of the five cases which are given, the third and fourth are crops of common ulcers from irritation; the third probably a chancre; and the first and second uncertain, but obviously not authorising mercurial treatment. Nor does it follow that because these patients did not apply afterwards for advice, that none of them had not secondary symptoms. The instances given under the second division are fungous ulcers, that might have followed simple ulcers from irritation, while others of them may have followed unindurated chancres, a portion of them only being the same which Mr. Evans means by *venerola vulgaris*.

Under that term, however, Mr. Evans condenses both the preceding kinds of ulcers, believing them to be one in two successive stages. He describes the *venerola vulgaris*, or *ulcus elevatum*, as "more frequently met with than all other ulcers of the parts of generation put together," and as presenting the following definite stages:—being pustules for the first four to six

days, scabbed till the tenth day, the scab covering a concave ulcer of the oval or circular figure, with a surface of a glossy brown, an unhealthy red, or more frequently a dirty yellow colour; from hence to the eighteenth day, the elevation of a fungous growth, above the surface of the surrounding skin, taking place and increasing: then follows a stationary period, after which the ulcer declines and heals, leaving eventually, where the thickening was, a permanent depression." In another passage Mr. Evans observes, "when situated behind the glans, at the junction of the integuments with the body of the penis, this ulcer has sometimes in its second stage an *excavated* appearance, like the calyx of an acorn; *in these cases there is often a great degree of hardness surrounding it*, which, however, seldom continues longer than through this stage, generally disappearing on the commencement of the third." So Mr. Evans's *venerola vulgaris* approaches very nearly, and probably was sketched from what I have described as unindurated chancre: my reasons for preferring my own account of the complaint, in which it is grouped with indurated chancre, to adopting Mr. Evans's systematic separation of *venerola vulgaris*, from that and other sores, are principally these: I believe, as I have already expressed, and as the last quotation from Mr. Evans seems to admit, that the induration in these sores is essentially variable; that all shades of it are met with; while, in each, the sore is truly siphilitic, which Mr. Evans denies. His *venerola vulgaris* he holds to be essentially different from chancre, and to be either not benefited, or made worse by mercury. Yet the following passage, which I shall further quote from his book, allows one to gather that he believed in one most important affinity between *venerola* and chancre. "The differences between *venerola vulgaris* and chancre," he observes, "consist, first, *in it not, as a general rule, being followed by consecutive diseases where mercury is abstained from*; secondly, in not requiring the excretion out of the venereal irritation for its cure; and thirdly, in that irritation being either useless or injurious."

Mr. Welbank, in his "Commentaries on Syphilis," adopts Mr. Evans's belief in the existence of *venerola*, as a frequent disease, pursuing a determinate

course, distinct from chancre. But he evidently finds great difficulty in drawing the line between the two, and in my opinion fails to do so. Nothing, however, can be more faithful than Mr. Welbank's own delineations of many features in siphilitic disease, of which I select some that may serve to fill up the picture already traced. "When chancre," observes Mr. Welbank, "is situated in the fossæ of the corona glandis, frænum, or prepuce, it is sometimes attended with considerable excoriation, which at first masks the more virulent complaint." Of chancres on the inner prepuce, situated near the glans and frænum, he remarks, that on retracting the prepuce so as to throw forward the ulcerated surface, the latter "will sometimes appear elevated in regular convexity, and exhibit a tawny or deep crimson colour." Of chancres of the integument, "they are usually of a deep red or tawny colour, more frequently oval than circular, and something raised above the common level." Speaking of primary siphilitic induration of the skin, he says, "convexity of the surface formed by large loose granulations, may be sometimes seen in the large tuberculated chancre, on the exhibition of mercury. The half healed, half excoriated, brown-red tubercle, then becomes of a raspberry tint, and exhibits large flabby granulations." Mr. Welbank, finally, adverts to the indurated and excoriated state of the extremity of the glans, when the orifice of the urethra is the seat of chancre; and he particularizes the flocculent, shreddy, or villous surface, which is often seen in ulceration of the glans.

It is an important desideratum to ascertain whether, according to Mr. Evans's conjecture, chancres without marked induration are less frequently followed by lues than the indurated ones. It is probable that this would at first, at all events, appear to be the case, as the accidental adoption by a common sore of the character of unindurated chancre must be easier and more frequent than going into cartilage-like induration.

Primary siphilitic disease is commonly already an ulcer before it attracts notice; so that any general account of its earliest appearance must be conjectural. But there is no reason to doubt that on an abraded surface, or an excoriation, the first appearance would be an ulcer; and when the skin is entire, opportunities

occasionally present themselves of seeing the disease as a pustule, and even as a vesicle containing an opaque lymph. The latter, it is probable, is the ordinary local commencement of the disease. I have seen the disease commence by a vesicle on the inner preputium, and existing, in its pustular form, on the skin of the penis. These observations are often to be made when, from neglect of cleanliness, fresh infection takes place from the original chancre.

A characteristic feature of siphilitic sores is, that they occur commonly but once, or at most two, at once. This, however, must no doubt be accidental; yet it is so constant a feature, that it is a useful aid in the diagnosis of ambiguous cases. A crop of sores appearing on the prepuce are sure not to be chancres. A crop of circular sores at the corona glandis following a suspicious connection, still most unlikely to be chancres, nevertheless occasionally prove of that nature.

The period which intervenes between exposure to infection and the appearance of a chancre is indefinite. It commonly varies from twenty-four hours to a week; but the interval may be much longer. "I have known cases," says Mr. Hunter, "where the chancres appeared twenty-four hours after the application of the matter, and I have known them seven weeks. A remarkable case of this kind was a gentleman who had not had sexual intercourse for seven weeks, when a chancre appeared, which was proved to be venereal by his having had the lues venerea from it, and being under a necessity of taking mercury." An instance came under my own observation in which the interval was something greater. A gentleman had a chancre upon the inner preputium, which he had known the existence of for ten days. He assured me that he had had no sexual intercourse for more than eight weeks before he observed this sore. Within a fortnight of the time I speak of, he was attacked with siphilitic psoriasis of the most virulent description.

It is through the experiments of Ricord that we are finally able to reconcile the anomalies that are observed as to the period of the appearance of siphilis, and to determine with certainty the mode of its development. These experiments, by the general uniformity of their results, establish that the indefinite time which intervenes in the ordinary

infection of siphilis, between contagion and the manifestation of the disease, is attributable to some agency external to the vascular cutis, the seat of which and the cause must be the epidermis, and its greater or less permeability in different parts and in different persons; and they prove that the order of the phenomena in the development of chancre, is, first, the production of a vesicle; that next becomes pustular; and then, breaking, discloses an ulcer. The experiments consisted in the inoculation of persons affected with chancre with the matter from their own sores on some other surface. M. Ricord usually made these inoculations upon the thigh. The following is the summary of his observations upon the artificial chancre so produced:—

"During the first twenty-four hours the point of inoculation reddens; from the second to the third day it becomes slightly swollen, and presents the appearance of a pimple with a red areola; from the third to the fourth day the epidermis, raised by a liquid more or less turbid, takes the form of a vesicle; from the fourth to the fifth day the turbid secretion has increased in quantity, and become purulent. The vesicle becomes a pustule, and having a depression in the centre, bears a resemblance to the pustule in small-pox. At this period the areola, of which the breadth and intensity of colour have increased, begins to contract, especially if the disease is not progressing; but from the fifth day, the subjacent textures, which often as yet have undergone no change, or which were only slightly oedematous, are infiltrated and hardened by the effusion of plastic lymph, which yields on pressure the resistance and elastic feel of cartilage. Finally, after the sixth day, the pus thickens, and a crust or scab begins to form: when this separates an ulcer is exposed, which, based on the firm texture that has been described, is hollowed to the thickness of the skin, and presents a surface of false membrane, white, or grey, or lardaceous. The borders of the ulcers are circular, cleanly cut, as if made by a punch, are nevertheless detached (*decollés*) for a greater or less extent, and when examined with the microscope, present shallow indentations, and a surface resembling that of the base. The skin immediately surrounding the ulcer is thickened, firm, slightly elevated at

its border, and is coloured of a reddish brown mixed with a violet tint."

M. Ricord mentions that he has thus inoculated from primary siphilic sores in more than four hundred instances, and that the result which has been described had never failed to follow. The few observations of the same kind which I have had a proper opportunity of making, lead me to attach great faith to M. Ricord's statements; but I think that he has given a degree of precision and accuracy of outline to his description of the artificial sore beyond what the facts may have warranted. I cannot say that I have observed the marked induration which he describes supervening at the fifth day, nor has the hardness ever amounted to more than I should express by the term firmness; such a firmness as from analogy should be produced by common inflammatory effusion into the texture of the skin surrounding the ulcer, and of the tissue beneath the surface of the ulcer. I certainly have not seen any thing approaching to the cartilaginous hardness of indurated chancre. I have found that in twenty-four hours from inoculation there has been a redness at the surface of the punctured part; that the next day there is lymph effused below the epidermis, or a vesicle; that by the third day there is a pustule, surrounded by a zone of red and slightly thickened skin; that the pustule breaking, a level circular ulcer, a little below the surface of the skin, has shewn itself, with a surface having alternate elevations and depressions, of a reddish grey colour, a little mottled. The circular edge of the ulcer I recognize to be indented with minute semi-circular notches, such as M. Ricord describes.

It may be observed, that experiments to produce venereal sores by inoculation had been made by several before M. Ricord, from Hunter downwards; but all that had previously been made were desultory or inconclusive; and to M. Ricord is due the credit of having first systematically instituted a series from which positive inferences can be deduced. M. Ricord appears, indeed, to believe that he has thus established a certain criterion between siphilic sores and sores of other origin. As affording a practical criterion, however, it will be seen that his method does not carry with it positive certainty: the result he obtains is only an approximation, and re-

quires to be corrected by the observation of the character of the primary sore, as I shall presently shew; not to mention that to be practical a method must be one which can uniformly be adopted. But there are obvious objections to the production of the artificial sore, of which not the least are the length of time necessary for its development, and its intractable nature, when it has been allowed completely to manifest its character. But, in a theoretical point of view, as settling some controverted points as to the common or different origin and nature of different venereal affections, M. Ricord's experiments appear to be not less interesting than conclusive.

In the same tables in which M. Ricord mentions having obtained the artificial sores from upwards of four hundred chancres or primary pustules, he mentions that inoculation in upwards of three hundred cases from secondary sores or pustules did not produce the ulcer in a single instance; thus completely confirming Mr. Hunter's experiments and conclusion upon the latter point.

Another opinion, however, entertained by Mr. Hunter, upon a point of still greater interest, the experiments of M. Ricord go completely to disprove. Mr. Hunter held that the poison of siphilis and gonorrhœa are one and the same, the difference of effect resulting from the different character of the surface to which the virulent matter is applied. M. Ricord's numerous experiments on this question, amounting to upwards of three hundred, followed only by negative results, may be considered as having set it at rest for ever\*. Nevertheless, it will be remembered that Mr. Hunter obtained an affirmative fact upon the point at issue, and that by an experiment upon his own person, in which he inoculated himself with gonorrhœal matter on the glans and prepuce, he produced sores that were not indeed indurated, but which were followed by attacks of constitutional siphilis. This experiment, considering who was the subject of it, author, observer, and narrator, has always been a stumbling-block in the way of those who wished to entertain the unqualified belief that siphilis and gonorrhœa are not the products of a

\* I think that the facts mentioned at pages 110-11 of M. Ricord's work only shew his candour, and do not the least impugn the validity of his general conclusion on the present point. However, others may think differently.

common virus. Of the various suppositions which would get over this difficulty, the circumstances of the following case point perhaps to the true one. I should observe, that I had several times inoculated persons affected with gonorrhœa from their own discharge, and, agreeably with M. Ricord's numerous observations, had found no pustule follow. But there was a patient who laboured at once under chancre of the prepuce and gonorrhœa, and whom I inoculated at the same time with the matter of both, taking care that the gonorrhœal matter used should be obtained fresh from the urethra, unmixed with any external secretions, and carefully applying sticking-plaster over both the punctures. To my surprise, when I expected that the one puncture would lead to nothing, and the other produce a chancre, equal and similar sores were simultaneously produced by both. The explanation of this occurrence I found to be the following:—There was a small chancre in the urethra, immediately within the orifice, which could be distinctly seen on pressing the lips of the urethra apart. It was no doubt from this source that the matter flowing from the urethra derived the quality which enabled it to communicate chancre; and I have little doubt that the result of Hunter's experiment, so much at variance with the number which have now been made with pure gonorrhœal matter with no effect, is to be attributed to the like cause—to the matter employed having been taken from an urethra which was at the same time the seat of chancre.

I entertain, again, little doubt that the various cases reported by so many, of the same woman infecting alternately with chancre or gonorrhœa, admits of the same explanation. The person who has communicated the two diseases has had them both. Some have been infected with the one, some with the other, some with neither. M. Ricord has established the fact that chancres often exist deep in the vagina or on the os uteri. I believe, from observation, that such chancres, not external, in women, may remain for months in an indolent and unprogressive state. I attended a gentleman for three successive chancres, which he had caught, at intervals of a very few months, from the same woman, who would have it

that she was in perfect health. At last she consented to allow me to examine her, when I found two small ulcers within the external labia, which got well under mercury. The story of the Portuguese opera-dancer, mentioned by Dr. Fergusson, and already quoted, is doubtless to be explained in the same way.

In some few of the instances in which I have used M. Ricord's method of identifying syphilitic disease, I have come upon further results, which appear to me strongly to favour the supposition that chancre and phagedænic venereal sores are derived from the same poison. I have in three cases of benign phagedæna inoculated the patient from the sore. There has, indeed, been some difference of opinion among those to whom I showed the suspected ulcers, in two of the cases referred to, as to their nature. One surgeon, whose judgment I respect very highly, was disposed to consider them serpiginous ulcers only, and something essentially different from phagedæna. And the ulceration was, indeed, superficial. Nevertheless, in all, but in one especially, to which I refer because the ulcer of inoculation derived from it was allowed to run its course for a fortnight, for the purpose of fully identifying its character, there existed the spreading yellow edge, the irregular figure, the one margin healing while the disease progressed at the other. The patient had had besides, upon the back of the thigh, an extensive phagedænic ulcer, of which the character was indisputable. This had but recently lost its phagedænic appearance, and was in progress of healing, the ulcer on the glans penis as yet remaining in the state described. Mercury, likewise, it may be mentioned, had been used in the earlier part of the case, and had done harm. Now inoculation in these three instances from sores which in my opinion were certainly phagedænic, produced a pustule similar in appearance to that caused by inoculation from chancre. In two of these cases I stopped the progress of the sore on the fourth day by touching it with nitrate of silver. In the third the ulcer was allowed to take its course, and exactly resembled the artificial chancre.

These facts on the one hand appear to me to confirm the opinion that chancre and phagedænic venereal sore proceed

from the same virus; and on the other, to detract from the value of M. Riord's method as a practical test of chancre.

I shall now attempt, by recapitulating the points of distinction which have been already described, and by adding what may be necessary, to define the practical line between other sores and true chancres; or to enumerate the circumstances by which an approximative diagnosis may be drawn between sores, on the one hand, that either do not threaten to carry lues into the system, or, if they do, can by no known means be prevented doing so; and on the other, those sores which, while they most threaten to produce constitutional lues, are yet, both in their progress and as regards their effects on the system, to a positive degree under the control of medicine.

Then it is evident that herpes and common excoriations are distinguishable by their appearance from chancre; that ulcerative and sloughing phagedæna are not less so, together with spreading superficial sores, whether called benign ulcerative phagedæna, or serpiginous ulcers.

The characters of the different varieties of chancre are likewise so clearly definable, that they cannot easily be overlooked. But if chancres ought not to be mistaken for common sores, common sores may unavoidably, looking to their present appearance alone, sometimes be mistaken for chancres. It has been mentioned that the little ulcer of herpes may, through neglect, spread, and resemble a chancre. Any accidental sore resulting from a heated state of parts, want of attention to cleanliness, the irritation of gonorrhœal matter, or the contact of other acrid substances, may again be circular, have an inflamed edge, and resemble chancre. But the causes enumerated may produce either one, or a crop of ulcers: if the latter, the presumption is strong that they are not chancres. If there be but one or two, the doubt as to their nature can only be cleared up (as in the sore following herpes) by waiting, and applying for a few days cooling remedies to the part. When such ulcers are just within the aperture of the prepuce, the latter being long, they are liable to be rendered irritable, and to be kept from healing, by the passage of the urine, and at the same time to become extremely indurated, the texture round

them being almost cartilaginous. Practically, again, one would be slow to set down as chancre an ulcer that one had only seen with a fungous, or soft, raised, and secreting surface. Finally, secondary siphilitic psoriasis will produce on the penis or scrotum appearances much like indurated chancre. But in all these cases the attendant circumstances and history will generally suggest doubts to the surgeon, which he has only to entertain to prevent his being misled. A few other sources of ambiguity remain, which, belonging to the subject of phimosis, will be spoken of with it.

[To be continued.]

## REPORT ON VACCINATION.

*To the Editor of the Medical Gazette.*

SIR,

HAVING acted as one of the Secretaries to the Vaccination Section of the Provincial Medical and Surgical Association, perhaps you will allow me to occupy a very small space in your valuable publication.

In common I should think with every member of the Section who was present at the meeting at Liverpool, I have read the two letters of Dr. Gregory with the greatest astonishment. At the meeting of the Section on the 24th July, Dr. Baron submitted the report to them, and carefully read every line of it. The Section unanimously adopted the report; Dr. Gregory himself being either the mover or seconder (I forget which) of such adoption, and expressing his approbation of it in the most unqualified terms. The following day the report was presented to the Association in full meeting, and again read by Dr. Baron; Dr. Gregory was present, but no word of disapproval fell from him. Nay, more, at the dinner, on the occasion of Dr. Gregory's health being drank, he in returning thanks went out of his way again to laud the report, and to express his high satisfaction with it; and paid a very high compliment to provincial practitioners, to one of whom, he observed, we were indebted for the discovery of vaccination, and that to the united labours of others we were now indebted for placing that discovery upon a solid and lasting basis.

What has occasioned the *new light* that has so suddenly burst upon Dr. Gregory, he can, of course, best explain; but I think it is only just to Dr. Baron, and to the Section, that the profession should be made acquainted with the facts I have stated.

The letters of Dr. Gregory, and of your correspondent, "Scrutator," call for some remarks, especially as regards the complaint of the latter, that so little use has been made in the Report of the information received from the Small-Pox Hospital—a circumstance that I think I can satisfactorily account for, if you will permit me to intrude upon your pages a short explanation in your next week's publication.—I am, sir,

Your obedient servant,

WILLIAM CONOLLY.

Castleton House, near Cheltenham,  
Nov. 5, 1839.

### *To the Editor of the Medical Gazette.*

SIR,

I took a good deal of trouble at the beginning of this year (when I could ill afford the time) about the Report of the Vaccination Section of the Provincial Medical and Surgical Association; and I therefore did not feel particularly gratified at the strictures of Dr. Gregory and Scrutator on this subject, which appeared in your last number. I made a point of calling on Dr. Baron, naturally expecting that he who had drawn up the report would feel anxious to rebut the attacks that had been made. He observed to me, however, that he had candidly acknowledged the only error that had been pointed out; that he was conscious that the report had been prepared with an honest intention and with great care; that it contained what he believed to be truth, and that he felt perfectly willing to commit the issue to time and the unprejudiced opinions of his brethren, when present excitement and irritation shall have passed away; and that for these reasons, and observing the spirit in which the controversy had been commenced, he felt no inclination to prolong it. Dr. Baron's feeling on this point may be correct; but I, as a member of the Section, and one who has bestowed no little labour in wading through a great mass of returns and correspondence, carefully examining their contents, and reducing

them to a tabular analysis for the sake of this very report, have a right to think differently, and act as best pleases myself. I am not therefore content that this valuable report should be quietly consigned to even temporary neglect by the flippant remarks of Scrutator, or the clever contrivance of Dr. Gregory. I am not content that a report which, as a whole, is marked by extreme care and fidelity, should have its veracity impeached and its value depreciated by the innuendoes and inferences of Dr. Gregory, who has the dexterity, by garbling the words and perverting the meaning, to distort a remark applicable to medical inquiries generally, so as to make that which was urged in extenuation of a particular inaccuracy, appear like a confession of haste and negligence in conducting the whole inquiry. I will copy the two sentences, because, when standing in apposition, they will best indicate the character of this manoeuvre, and preclude the necessity of my affixing any epithet to it.

"The examination of a great multiplicity of documents, and the hurried and broken manner in which medical men are for the most part constrained to carry on their inquiries, will in some degree explain, if it does not altogether excuse, the mistake which has been committed."—*Dr. Baron, Med. Gaz., No. 621, p. 176.*

"It is certainly much to be regretted that an error, or rather a series of errors, such as those I pointed out in my last communication, should have occurred in Dr. Baron's report, because it leads naturally to the inference that the same 'hurried and broken manner of carrying on the inquiry,' to which Dr. Baron attributes one imperfection, may have led to others."—*Dr. Gregory, Med. Gaz. No. 622, p. 209.*

But, not to dwell further on these points, I am prepared to contend that this Report is a very excellent one, and am ready to meet any arguments which may be fairly brought forward in order to prove that it is not so. I maintain that the facts therein detailed are recorded with scrupulous care and exactness, and that the pathological inferences from them are drawn according to the principles of fair and legitimate deduction. I can show that the doctrines which the Report advocates are supported by a body of testimony from dis-

interested and incidental sources which the opponents cannot gainsay, and that they therefore do well to persist in fastening with appropriate pertinacity on a solitary blunder. I contend that the points objected to by Dr. Gregory are capable of as much proof as the subjects of medical science generally admit of, and that Mr. Ceely's experiments will tend to *remove prejudice, secure correct and satisfactory practice*, and lead to the conviction that vaccination and varolous inoculation are *on a par* in respect to their power of securing the constitution. There will be no difficulty in making it manifest that the whole reasonings in Dr. Gregory's letter are remarkably inappropriate and deceptive; and very solid and sufficient reasons can be assigned for the omissions in the Report complained of by Scrutator. In establishing these points, I believe that no provocations will betray me into using any harsh or intemperate expressions, and I will endeavour to make my observations as brief and pertinent as possible. I fear, however, that fully to enter upon, and do justice to the subject, would encroach too far on the limits you could conveniently allow me in your one number. The estimate which a writer and an editor form of the importance of any communication is often very different; and an editor may, unintentionally but very effectually, cripple an argument, when he merely wishes to reduce it to a convenient length. I think, therefore, in the present communication, I had better confine myself to specifying the points which I am ready to advocate and defend, and indicating the spirit in which a discussion of this kind ought to be conducted.

It is quite immaterial to me whether or no Dr. Gregory may choose to notice this letter. If he should please to enter into the controversy with me, I should like to intimate to him, at the outset, that in professing to quote an opponent's words by putting them between inverted commas, it is always right to quote them exactly, although it may not be quite so convenient. With respect to Scrutator, I have to remark, that, although I like for a man to attach his real name to his writings, I am not very fastidious in the matter, and shall not object to his retaining his fictitious appellation if he thinks it necessary, or finds it particularly agreeable. I wish, however, to suggest to him that it is rather indecent, or at

any rate not in good taste, for a person disguised under an assumed name to make use of violent and irritating expressions, and that the best that can be said of anonymous abuse is, that it is a very *discreet* exhibition of valour.

I am, sir,  
Your obedient servant,  
HENRY COLES.

#### ANALYSES AND NOTICES OF BOOKS.

---

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

---

*A Challenge to Phrenologists; or Phrenology tested by Reason and Facts.*  
By A. M. of the Middle Temple.  
London, 1839. Small 8vo. pp. 206.

THE chief practical objection to phrenology is the one urged by Dr. Prichard, that the exceptions to its rules are at least as numerous as the examples. Hence if phrenology is called a science, it must be called so with the admission that its foundations have yet to be laid; though we should rather be inclined to consider it as a tentative art, not unworthy the attention of thoughtful and candid men, with leisure to investigate truth, and willingness to acknowledge their errors. Our author, however, who writes very jocosely and entertainingly, refuses to concede the phrenologists any thing. He not only laughs at their mistakes most unmercifully, but denies them all truth and merit in a department where they deserve some commendation; we mean the depicting of the shades of human character, and the discrimination of cognate qualities. Thus, Gall says he discovered the organ of cautiousness in the following manner.

“At Vienna he knew a prelate of *excellent sense and considerable intellect*. Some persons disliked him, because through fear of compromising himself, he infused into his discourses *interminable reflections*, delivered with tiresome slowness. In conversation *he was cautious* in coming to conclusions. He was continually pausing in the middle of his sentences, and repeating the beginning of them over and over again before proceeding further. *A thousand times he exhausted Dr. Gall's patience*. Never in his life did he happen by any accident to give way to the natural flow

of his ideas, but would constantly recur to what he had already said, and consult with himself, whether he could not amend it in some point." "*He acted just as he talked.*"

This is certainly a lively portrait of a hesitating and over-cautious man, though A. M. of the middle Temple can see nothing in it "but a prudent man *habitually thinking* before speech or action, the precise contrast of Dr. Gall's own character."

No. 28, it seems, is the organ of number, which gives the conception of number and its relations. Now, we have nothing to say in favour of the existence of the organ of number; but we are convinced that there is an arithmetical faculty, which is far more developed in some men than can be accounted for by education or practice; a power, in fact, which is seen at the first dawn of reason, and makes a calculating boy of the son of the humblest peasant. A gentleman mentioned in Mayo's Physiology stated that his mental multiplication table reached to 1000; "a remark," continues Mr. Mayo, "which seems to me to throw light upon the nature of this extraordinary talent, or to show it to be the same in kind, though incomparably superior in rapidity, as that which common persons may acquire by practice. It is but in its extent, facility, and rapidity of combination, that genius differs from ordinary ability." With this we agree entirely; not so with what follows by the Templar:—

"Finding, then, as we invariably do, that men's calculating powers depend altogether upon the extent to which they are compelled to employ themselves in arithmetic," &c. &c.—(P. 162.)

Instead of "invariably do," read "invariably don't;" the progress being by no means proportioned to the labour bestowed; how many scores of years would it take to bring up an ordinary lad's arithmetic to the pitch of Mangiamela, the Sicilian boy? It is encouraging to know that with rare exceptions we can all of us learn to run; but it is sheer madness to assert that we can all succeed in running like the swift-footed Achilles.

On the whole, A. M. has the air of being somewhat young and hasty. As a notable example, he imagines that all truly scientific men are materialists (p. 12), which is very far from being the case. Physiologists, as well as the mass of mankind, have been cheered by

the belief, that the reasoning faculties are distinct from the tenement which they inhabit, and that in some favourable instances,

"The soul's dark mansion, battered and decayed,  
Lets in new light through chinks that time has  
made!"

*The Anatomist's Manual; or, a Treatise on the Manner of Preparing all the Parts of Anatomy, followed by a Complete Description of these Parts.* By J. P. MAYGRIER, M.D.P., Professor of Anatomy and Physiology, &c. Translated from the last French Edition. London, 1839. Small 8vo. pp. 564.

THIS book is intended to combine the advantages of a compendium of anatomy, and a dissector's manual, with instructions for making anatomical preparations. Dr. Maygrier appears to have that laconic clearness for which good French writers are so celebrated; but the translation is not well done. If the English student follows this book, he will too often learn a language different from that of his fellow anatomists. Thus we find "rib of the omoplate" for inferior costa of the scapula; and "coracöid apophysis" for coracöid process; the word *process*, indeed, as far as we have seen, never occurs in the translation. *Echancures* is used for notches at p. 46, and *pröeminente* for prominent at p. 47; *paroïs* for parietes at p. 353; the *peristaphylin muscles* for the levator palati and circumflexus or tensor palati, p. 215; and "S' of the colon" for sigmoid flexure of the colon, p. 329. At p. 368 we find the phrases "medullary bandelette," "medullary cordons," and "pituitary tige." Translation is by no means the easy thing that it is vulgarly supposed to be.—*Experto crede.*

## MEDICAL GAZETTE.

Friday, November 8, 1839.

"Licet omnibus, licet etiam mihi, dignitatem  
*Artis Medicæ* tueri; potestas modo veniendi in  
publicum sit, dicendi periculum non recuso."  
CICERO.

## MEDICAL RELIEF UNDER THE NEW POOR LAW.

WE concluded our last article but one with the remarkable case of a young man

who being a petitioner for relief, was sent to a cell in a jail already occupied by two persons who had the itch; and who contrived to make his escape from this charitable asylum, but not before he had caught the disease. This is the most stringent "test of destitution" that we have yet heard of, and is, we should hope, unmatched, even in the annals of the Act. But granting that the understrappers who are entrusted with the execution of the statute, have never before pushed their frenzied obedience so far, it is obvious to every one who notes the events of the day, that the ardent desire to make workhouses distasteful, nay, intolerable to their occupants, has carried the friends of the new system beyond all defensible bounds. It is equally plain, that it must be extremely easy to effect this object, even without going so far as to inoculate applicants for relief with the itch. Any disciplinarian of ordinary cleverness might reduce the population of his workhouse to the required amount; he might easily manage to drive every one out of his fastness who had legs to carry him, and out of five hundred inmates retain only half a score of paralytic sufferers. No one has hitherto gone quite this length, but bold attempts have been made towards it. Naturalists inform us, that the rhinoceros, though musket-proof in other parts, may be wounded in the belly; and thousands who would be insensible to other species of worrying, are driven out by the prolonged process of fasting.

Yet after all these refined inventions for making the refuge of indigence unbearable, we still hear occasionally of some one who affects to be surprised or displeased that A did not apply for relief, and Z did not go into the workhouse. The rich man, like the Sybarite in the story, cannot sleep if one of the rose-leaves that form his couch is doubled under him; but if he hears that a poor

man cannot repose on a bed of thorns, his astonishment is unspeakable.

About two months ago, an inquest was held at Kensington Gravel Pits, on the body of John Dale, an infant thirteen weeks old. The verdict of the jury was "natural death;" but as it appeared that the mother of the deceased was miserably poor, having been deserted by the man with whom she lived, the question arose, whether she would not have done better to go in the workhouse, as she had been advised by some magistrates. "There was no proof," said the Coroner, "that the mother had been guilty of neglect, although she had certainly been guilty of an error in judgment in refusing to go into the workhouse when it was wished\*."

What may be the precise amount of suffering in the Kensington Workhouse we do not know; but if it is an error of judgment to refuse to go into such a place, we would appeal to the party, who pronounced this opinion, whether great efforts are not usually made to lead the poor into this error.

To take another instance. An inquest was held at Mile End, New Town, before Mr. Baker, on the body of a child, aged 3½ years, named Right; and the verdict was, "that the deceased died a natural death by the visitation of God, brought on by want and disease, and extreme privation, and want of care." The mother, a squalid creature, said that her reason for not applying for parochial relief was that she had done so some time ago, and got so abused that she had not the heart to repeat her application†.

But we will forbear all further comment on these dreadful events, and pass on to the more immediate subject of this article—the medical relief of the poor under the new Act. A letter upon this important branch of national charity,

\* Times, Sept. 18th, 1839.

† Ibid. Oct. 24th, 1839.

written with the usual ability of Serjeant Talfourd, appeared in our number for Sept. 21st, 1839, p. 973.

The first question considered by our learned and excellent ally, is the appointment of an additional commissioner, who is to be of the medical profession, and who is to act with the others in all points concerning medical relief, but who is not to vote on other discussions. This proposition is extremely good; for we must charitably allow that the mistakes of the present commissioners are in part attributable to ignorance; they have dealt out heavy blows and great discouragement to poverty, and the worst of it is, they have dealt them out in the dark. In future, if the medical commissioner is of tolerable mettle, his lay associates will not be able to plead want of knowledge as their excuse. The only qualification we see mentioned for the medical commissioner is that he must be a physician or surgeon of five years' standing. This qualification is easily found; but the temper and talents required for such an office, the faculty of nicely adjusting the right and the expedient, are rare indeed.

It is pretty clear that his opinions must be of a good presentable medium between humanity and utilitarian sentiments. If he thought much of healing the sick, and little of lowering the rates, he would be called a tender-hearted simpleton, perhaps even a philanthropist, and must expect to find himself in a constant minority. Every one has read of impish orgies, which are suddenly broken up by the utterance of some sacred words; and we should imagine that any one bold enough to pronounce the phrase—"rights of the poor," in a Somerset-House conclave, would produce as sudden an adjournment, as in those assemblies on the Harz Mountains. Publius Syrus observes that your deicer, the more skilful he is in his art, the

worse he is as a man\*. In like manner, your commissioner, the worse he was as a man, the more skilful would he be in lowering the rates; like the *aleator* of Publius Syrus, he would throw double sixes for himself, and deuce-ace for the mass of mankind!

It once happened during the bad old times, that Colonel Thompson, having sat upon a Court-martial where the prisoner was found guilty, proposed one hundred and fifty lashes as his punishment; but this number was so infinitely below the high-flown conceptions of those days, that he was asked by his brother-officers whether he meant to make a joke of the service? And we fear, that if a stout-hearted medical commissioner were to venture to tell his lay brethren what is really wanting for the relief of the suffering poor, he would be asked if he meant to make a joke of the Act. His three opponents would cry out, *quocunque modo rem*—a saving at any price!

Yet there is one misrepresentation of the economists which he ought to correct; it is the pretended statement of the quantity of food consumed by different classes in England, with the addition of what is given to transported criminals. This choice morsel, drawn up as a table, has been for years most extensively circulated, and has doubtless had its share in promoting the schemes of starvation. It has even made its way into France, where we find it in an article on Penitentiaries, contained in the *Gazette Médicale* of Sept. 21st, 1839. The translator has made the mistake of putting *par jour* instead of *par semaine*, but has otherwise, we believe, translated this precious little document very faithfully. Artisans at the highest wages, says the table, eat 140 ounces a week. Now this is just twenty

\* *Aleator, quanto in arte est melior, tanto est nequior.*

ounces a day, or one pound avoirdupois and a quarter. Let us suppose this to consist of a pound of bread and four ounces of meat; what a wretched apology for a meal! But then these frustules are to serve for three meals; so we can only have half-a-pound of bread and the scrap of meat for dinner, four ounces of bread for breakfast, and the same quantity for tea or supper. Even in dear times the bread and meat will cost but fivepence; *i. e.* twopence-halfpenny for a pound of the former, and the same sum for four ounces of the latter; so that we imagine few picked workmen, earning from thirty-five to forty shillings a week, would push their asceticism quite so far. But it was necessary for the table. The highly-paid artisan comes immediately above the labourer, who is at starving point, marked by 122 ounces on the scale; and immediately below the workhouse poor, whose degree is 150. The next on the table are soldiers, who are supposed to eat only 168 ounces a week; this is twenty-four ounces, or exactly a pound and a half avoirdupois a day. We would request our readers to take their scales, and weighing out a pound of bread, and half a pound of meat, to calculate by their eye, or by a still more practical method, whether such a modicum would suffice for the daily invigoration of a colossal guardsman or grenadier. They will unanimously exclaim, "No!" and that there must be a mistake in the table; and so there is, for we learn from Dr. Hennen, Inspector of Military Hospitals, that a soldier has a pound of meat and two pounds of bread daily, making exactly double the supposed quantity. It would be truly strange if he had neither cheese, butter, nor vegetables, any one of which would add still more to the mortification of the economists. Four other classes follow, who are all (tabularly) better fed than soldiers; the fourth and most luxu-

rious class of all being the transported, who are represented as consuming 330 ounces a week. This seems likely enough, as far as regards domestic or farm servants; as it is probably the minimum that will satisfy the cravings of a healthy stomach, and the farmers of Australia find it to their interest to have well-fed labourers. It must be unpleasant, at the best, to have servants in one's house, or on the grounds, who are all professed scoundrels; but a burglarious cook, or sheep-stealing footman, will not have so sharp an edge on his villany, if sated, as if starved. Hence it is clear, that if low diet is to be part of the punishment of transportation, this can only be effected by employing the convicts in government works; and the sole use of the convict number of ounces at the top of the table, is to show the quantity required by the honest labourer.

The second point considered by Serjeant Talfourd is the limitation of medical districts. It is proposed that no district entrusted to a single medical officer shall contain more than sixteen square miles, or a population of more than five thousand; except in towns, where a district of four square miles may include six thousand inhabitants; or of one square mile, ten thousand.

These limitations are, of course, excellent as far as they go, and will cut down many of the present districts. Yet those districts that come up to the maximum will still be too large, or too densely peopled. For even if the surgeon pursued his patients into the remotest nooks of his district on an untiring steed, those of the sick who must come or send to him would find the distance inconvenient, or, indeed, in many instances, prohibitory.

If a district of sixteen square miles forms a perfect square, which is the most favourable supposition, each side will be four miles in length, and a pa-

tient living at one corner will be more than five miles and a half in a geometrical straight line from the surgeon living at the opposite one; or, allowing for the winding of roads and lanes, about six; so that some one must walk twelve miles for the required mixture. This is an extreme case; but walks of five, six, or eight miles, will be too common. "My time is my estate," said a shrewd Italian; and rather than waste half the day in walking and waiting, the poor will abstain from the relief so uncomfortably proffered.

If a union, again, contains 10,000 inhabitants, during a sickly season the pauper patients will be beyond all visitable number; who can attend to 150 or 200 patients?

On the 19th of last September, an inquest was held at Northfleet, on the body of Harriet Court, a girl of 18. Mr. Parke, one of the surgeons of the North Aylesford Union, was sent for, and promised to come in the afternoon; "he had so many patients to attend, he did not know which to go to first." The verdict was—"Died by the visitation of God," to which the jury added, "that it is their opinion the medical arrangements under the new Poor Law Bill are both inefficient and cruel in their operation, and they cannot separate without expressing that opinion to the coroner." Mr. C. J. Carttar, the coroner, expressed his concurrence\*.

These cases are, unfortunately, so common, that it is scarcely necessary to quote them; yet, when the question in debate is the size of districts, it is proper to show the effect of large districts, dense population, and inadequate salaries. Why mince the matter? Is it not clearer than the day, that scanty pay will produce negligent attendance? If the union surgeon will zealously attend the poor for his nominal salary of fifty

or sixty pounds a year, we have no words to express our admiration of his benevolence; but we cannot get a thousand Howards at our bidding, and we must address ordinary motives to ordinary men.

With respect to the remuneration of the medical officers, Serjeant Talfourd proposes the establishment of a maximum and a minimum, but does not state what either should be. If we might be allowed to give a vote in so delicate a matter, we should say that £100 a year is a very paltry pittance for the smallest union known; it is about 5s. 6d. a day, a sum for which an attorney would not write a letter.

The last subject touched upon is the qualification of the medical officers. If he dispenses medicines, he must be a Licentiate of the Apothecaries' Company. Surely this is an unnecessary restriction; a retired army or navy surgeon, though he may never have appeared before the Worshipful Society, can make up pill or powder in the Highbury Union as well as he did in the Peninsula, or the Mediterranean; we would not go so far as the author who published a book called "*Medicine no Mystery*," but certainly dispensing medicine is none. Perhaps it might be well to require either the diploma of physician from a university requiring residence, or the license of the Hall, from civilians; but the proposal is to make the Blackfriars' examination indispensable, as if it carried some special virtue in its train.

"It is also proposed, that if the district shall contain a medical practitioner duly qualified, who has resided for six months within it, desirous of undertaking the trust, he shall be preferred to a stranger."

This clause seems to have been rendered necessary by the conduct of the Commissioners, who have too often abused the immense power they possess, by sending down hungry clients from

\* Times, Sept. 20, 1839.

London, to undersell the practitioners of a country town, probably already ground to the earth by homebred competition.

We are glad to hear from Serjeant Talfourd, that there is "a gratifying alteration in the tone of the Commissioners:" *veritas est magna, et prævalebunt.*

His letter is admirable; we would wish every one of our readers to peruse and digest it. It is satisfactory to think that with such an advocate, our cause, which is in every sense the cause of the poor, is sure of attention: there is an echo in England if one but utters the words—justice and humanity.

#### SUCCESSFUL TREATMENT

OF

#### ERYSIPELAS BY RAW COTTON.

Dr. F. M. ROBERTSON, of Augusta, Georgia, in a communication in the Southern Med. and Surg. Journ. (July, 1839,) states, "that he has employed raw cotton, in the treatment of erysipelas, as recommended by M. Reynaud, with very satisfactory results. Two cases in which it was employed are related. One of these was a little girl who had a week previous accidentally received a small wound, which penetrated through the scalp to the cranium. The wound had suppurated, and on close examination, Dr. R. found that it had taken on erysipelatous inflammation, which had extended to the right ear, and, on the forehead, as far as the nose, and appeared to be progressing over the entire scalp and face. It was in the afternoon when Dr. R. saw her: during the morning the febrile excitement was high, and she had been, occasionally delirious. Dr. R. immediately had the hair cut as close as it could be, with a pair of scissors, and a cold bread and milk poultice applied to the wound, and the entire scalp of the forehead covered with the bats of cotton, as in the former case, at the same time, a dose of calomel, to be followed by Epsom salts, was administered. The relief from the cotton was immediate; all the bad symptoms were relieved, and, after the operation of the medicine, the general excitement was moderated and the delirium did not return again. In this case the inflammation progressed as far as the cheeks, and to the left ear. The cotton could not be applied over the eyes and nose, as the

patient was too young to understand the importance of submitting to such a cumbersome application; it, however, arrested its further progress from the cheeks and scalp. All the local symptoms were relieved as soon as the cotton was applied; no blisters formed on the forehead or cheeks, and the desquamation of the cuticle was very slight: much less than I have ever seen it in the mildest case of this disease, when treated without cotton. During the progress of this case, which lasted for seven days, the only internal medicine administered, except the first cathartic, was an occasional saline aperient and cold lemonade or soda water, made by dissolving the common soda powders of the shops.—*American Journal of the Medical Sciences.*

#### YELLOW FEVER.

*To the Editor of the Medical Gazette.*

SIR,

SEVERAL weeks ago I transmitted a letter for publication in the MEDICAL GAZETTE, being a reply to one from Surgeon Fergusson, of the Royal African Corps, setting forth the contagious nature of yellow fever whenever it appeared on the Western Coast of Africa, with the exception of Sierra Leone, where Mr Fergusson stated "it was ever the undoubted product of the colony itself;" but that at all the other stations of the coast it could have no existence unless it was imported in ships. As this doctrine appeared to me to be equally erroneous and pernicious, I wrote an answer to it; but I now perceive, in the number of the MEDICAL GAZETTE just published, that you decline giving it insertion on the same terms (and I can admit of no other) as those you accorded to Surgeon Fergusson. *Audi alteram partem* is a maxim of no more than the commonest justice; and the public journalist who refuses it must be understood as advocating a particular set of opinions only, and as no longer holding the balance of even justice, or making truth the object of his search through the channels of fair lengthened discussion. He, in fact, lends his pages to the spread of what I, and a great majority of the most experienced medical officers of the army and navy, consider to be an abuse and poison of the public mind on a most important question of medical science; supporting it by the authenticated signature of a medical officer, who, by the act of publishing, challenges me and all the world to the discussion; and immediately thereafter closes them (except on unfair terms) against the antidote that very challenge called forth. I did not begin the controversy; it was forced upon me;

and yet you refuse me a hearing. Is this fair between man and man? From your character and station in the world you must know it to be far otherwise. The *MEDICAL GAZETTE* has hitherto supported an unblemished reputation for impartiality; but that reputation will be tarnished in the estimation of every honourable mind, should you still deny a place in its pages to my original letter, or, failing that, to the one I am now indicting.

I remain, sir,

Your most obedient servant,

W. FERGUSSON M.D.

Inspector-General of Hospitals, H.P.

Windsor, Oct. 28th, 1839.

[We hope that Dr. Fergusson is now satisfied! Any one, we presume, on reading the preceding letter, would suppose that his name-sake, of Sierra-Leone, had made especial reference to him, and that a controversy had been going on which we now chose abruptly to terminate; but the fact is, that the party to whom he wishes to reply, has made no reference whatever to Dr. Fergusson, and that admitting his communication would be to originate a new discussion on an uninteresting subject. Our respected correspondent at Windsor attaches much more importance to the disquisition on the yellow fever than we imagine our readers generally do; and we feel assured that they will not find fault with our confining all argument on the subject to our extra-limitis department: a determination from which the above letter does not induce us to swerve. —*Ed. Gaz.*]

### ADDENBROOKE'S HOSPITAL.

DR. HAVILAND, Regius Professor of Physics in Cambridge, has resigned the office of physician to Addenbrooke's Hospital. His successor is Dr. Paget, of Caius College.

### BOOKS RECEIVED FOR REVIEW.

A Practical Treatise on the Diseases of the Eye. By William Mackenzie, M.D., Surgeon-Oculist in Scotland in ordinary to her Majesty, Lecturer on the Eye in the University of Glasgow, and one of the Surgeons to the Glasgow Eye Infirmary; to which is prefixed an Anatomical Introduction explanatory of a Horizontal Section of the Human Eyeball. By Thomas Wharton Jones, Surgeon. Third edition. Longman & Co.; pp. 923.

A Dictionary of Materia Medica and Practical Pharmacy, including a translation of the Formulæ of the London Pharmacopœia. By William Thomas Brande, &c. &c. &c. Parker; pp. 591.

Illustrations of Osteology. By Theodore

S. G. Boiragon, M.D., Physician to the Cheltenham Dispensary. Highley.

Commentaries on Diseases of the Skin. By Anthony Todd Thomson, M.D., &c. &c. With illustrations, drawn, lithographed, and coloured, by Mr. Joseph Perry. Fasciculus I. containing Leprosy. Taylor and Walton.

Elements of Physiology. By J. Müller, M.D. of Berlin. Translated from the German, by William Baly, M.D. Illustrated with steel plates and numerous wood engravings. Second edit. Part I. containing General Physiology, the Blood and Circulating System, the Lymph and Lymphatic System, Respiration, Nutrition, Growth, and Reproduction. Taylor and Walton; pp. 471.

Anatomical Plates. Edited by Jones Quain, M.D., and W. J. E. Wilson. Division IV.—Viscera, VII. containing the Minute Anatomy of the Liver, beautifully illustrated. Taylor and Walton.

A Treatise on Obstetric Anscultation. By Dr. H. E. Naegele. Translated from the German, by Charles West, M.D., &c. Renshaw; pp. 120.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF  
SURGERY.

*Delivered at the Westminster Hospital School,*

BY BENJAMIN PHILLIPS, F.R.S.

INFLAMMATION—continued.

*Value of external signs; how produced—Succession of changes—Stases—Changes in the blood—Its vitality?—Accidental secretions—False membrane—Induration—Softening—Summary—General principles of treatment.*

UNDOUBTEDLY the local phenomena of inflammation constitute, when co-existent, an incontestable evidence of the existence of that morbid condition, but taken separately they do not offer the same value. The *redness* may be simulated, in all its forms and all its shades, by any mechanical obstacle to the venous circulation. Again, it is necessary to be on our guard, in examinations after death, against the congestion and colour produced in certain parts by position. Inflammatory redness is much lessened after death; Bichat even insisted on the possibility of its complete disappearance in all parts: in the case of membranes it may no doubt happen, but only in slight cases. Though *pain* may be one of the most constant signs of inflammation, yet it may be wanting in chronic inflammation, and even occasionally in acute when the texture of the part is so lax as to lend itself easily to expansion. Still when pain exists, it follows inflammation so closely that it may be regarded as a fully exact measure of its increase or diminution. *Heat* is very closely attached to acute inflammation, and is rarely wanting; but its absence, as well as that of pain, is a fundamental

character of many chronic inflammations. *Swelling* may belong to a great number of lesions of nutrition other than inflammation. Therefore we hold that there is none of these local signs, though they may be usually most appreciable, which possesses a decided value. The accidental products of secretion alone furnish the true pathognomonic signs of inflammation, and among these lymph and pus hold the first place.

The *redness* is explained by the plentitude and increased caliber of the capillary vessels, and by the formation of new ones. The state of the blood in these vessels explains the different shades of inflammatory redness. Already, without the microscope, it had been said by Hunter that the intense redness of certain inflammations could only be explained by assuming, that the red blood passed unchanged from the arteries to the veins. We have seen that microscopic experiments perfectly demonstrated this phenomenon. Again, when inflammation is confirmed, microscopic experiments have shewn the blood gradually losing its globular appearance, and becoming darker in colour: these observations agree with those made by Hunter on the influence of the stases of the blood on its coagulability and colour, and account for the various shades presented in inflammation. The *swelling* is accounted for by the repletion of the vessels, the formation of new capillaries, and the infiltration of the tissues by the products of accidental secretion. *Heat* is owing to innervation and the movement of the blood, but its increase will be in a pretty exact ratio with the activity which will be impressed upon the inflammation by these two sources of its production. As to *pain*, as it is impossible, says Hunter, that any extraordinary operation should be established in the body without sensation making us aware of it, we cannot suppose that the rapid change of the natural condition which supervenes

in an inflamed part should occur without producing a sensation which may amount to pain. Those organs even, where nerves have not been discovered, become painful on inflammation. The explanation of this subject, which has been embarrassing—which was one of the grounds which induced Bichat to maintain, that innervation had nothing to do with inflammation—indicates nothing else than that inflammation demonstrates nerves where the scalpel cannot. As to those parts manifestly provided with nerves, it would seem easy to interpret the pain by the lesion of these nerves. Men have sought to ascertain whether the lesion were hypertrophy, distension, or other tangible state; but they have not succeeded: and this is not astonishing, says Hunter, "the nerves are only simple messengers of intelligence, which have nothing to do with organic phenomena." Although we may not be disposed rigorously to adopt this opinion of Hunter, it is nevertheless true, that we know not in what consists the modifications which the nerves suffer in inflammation; their distension and their irritation by the afflux of blood is conceived, and may be reasonably adopted.

Inflammation commences, then, it is very evident, by an innervation which may be called *plastic*, the immediate effect of which is to direct certain fluids to the seat of irritation. The blood is not only forced, as it were, into the capillary vessels of the irritated organ, but fixed and retained there. Now that which retains it is not a mechanical obstacle opposed to its return; on the contrary, it is a vital disposition, to which some pathologists have applied the term *spasm*, but as spasm would imply constriction, the term is clearly inapplicable. It is clear that certain vital, and at present inappreciable changes, render inflammation dangerous or otherwise; the danger rarely bears any very direct relation with the physical and material signs. In fact, in cases of violent death as a consequence of inflammation, we are surprised on opening the bodies at the very insignificant traces of organic lesions which are presented. Take, for example, acute pericarditis; what do we find after death? Some arborizations—a reddish marbled colour of the serous membrane; whilst tissues deeply inflamed have not occasioned during the life of the subject any considerable disturbance. Now the changes which are brought about in the capillary system of an inflamed organ have, as we have seen, been made the subject of careful examination. This net-work, upon which the stimulus is fixed, is destined to react against it; it becomes the seat of greater vital activity. This is proved by the pulsations which are felt, the heat which is deve-

loped, the sensibility which is exalted, and the secretions which are poured out. It is then the capillary system which is the seat of inflammatory action, and not the cellular or parenchymatous tissue, as was maintained by Platner, Haller, and Brandes. That the congestion of blood which irritation determines in a part manifestly dilates the capillaries of a part, is shown by the experiment of John Hunter on a rabbit's ear, and by others. It is not important to seek to determine, whether the capillary vessels are, or are not, endowed with a true contractility, and, as a consequence, capable of exciting the phenomena which are attributed to their increased activity. If after the opinion sustained by many persons, and reproduced by Magendie, the arteries have only a contractile action, by means of which the blood is pushed out through the capillary tissue into the veins, the capillary system itself is not endowed with any action. Now the experiments of Thomson upon the web of the frog's foot, in which it is easy to follow the course of the blood in the smallest vessels, clearly demonstrates this contractility: similar results were obtained by Hastings, Kaltenbrunner, and Gendrin, who having employed different stimuli, observed under the microscope the dilatation of these vessels, and their passive state after strong and repeated contractions.

There is, then, in an inflamed organ not only a decided congestion or stagnation of blood, as a consequence of irritation—there are not only physical and apparent changes in the affected tissue—but it becomes also a seat of irritation *consequent* upon this state of things, and this irritation may be propagated to the whole system, and constitutes *reaction*. When this is very considerable, *fever* is the result. There is not, in fact, any inflammation, if a little intense, which does not light up consecutive fever; and here we may say with Frank, "that fever is to the principal disease what the shadow is to a body (*febris certorum malorum potius umbra quam ipse morbus est.*") We may, however, see an opposite state of things; we may see fevers lighting up local inflammation. Force a horse to his speed, and maintain it long—hunt a stag, or other animal; his agitation will be great, his arterial system will be violently agitated, the blood will be pushed with great force into the capillaries, and you will find on opening him after death, unequivocal traces of inflammation in many organs. There are many cases where fever precedes the local affection. Is bubo or carbuncle manifested as a first phenomenon in persons affected with plague? Does the gangrenous sore throat precede certain fevers?—the efflorescence of the lips certain

ephemeral fevers?—the pustules of small-pox, the patches of measles or scarlatina, do they precede the fever? I say, certainly not; therefore, it is evident that general excitement may produce local inflammation.

The series of organic lesions and functional disturbances by which inflammation is characterized pass through many distinct periods. It is at first a simple congestion, accompanied by a certain redness, but with that exception the tissues present no anatomical characters which do not belong to them in the state of health, neither are the functions of the organ much disturbed. This congestion, during which microscopic examination has shewn us that the capillary circulation is alone excited, is not inflammation, and, if this state be dissipated, inflammation will not occur. Kaltenbrunner, as we have seen, carefully observed the capillary action which marks its diminution, and has shewn the kind of critical secretion, sometimes serous, sometimes sanguinolent, which it leaves here and there in the cellular tissue. When, on the contrary, the congestion is only the first period of inflammation, the redness increases, the organs tumefy, their consistency diminishes. This is the period of the stasis of blood in the capillaries; it is that of confirmed inflammation. This course of inflammation is more or less rapid; from this comes its distinction into *acute* and *chronic*, the exact limits of which it is difficult to determine. The development of the periods of inflammatory action, whatever may be the duration, affects the continued type, from beginning to end, and always requires a certain time for its accomplishment: it can never assume an intermittent type, as some think; it cannot exist and be dissipated in a few minutes. Those statements, it is evident, can only refer to simple congestions, transient as the stimulus which excited them, and which have never acquired intensity enough to light up a true inflammation.

Having exposed at sufficient length those observations which are most entitled to credit, relative to the state of the capillary vessels in a state of inflammation—because it is the foundation of modern pathological anatomy, and the only legitimate basis for a theory of inflammation—it can hardly be necessary for me to occupy your minds with the theories of Brown and his disciples, or those of the partisans of the philosophy of nature. It was clearly not by pathological anatomy that the *incitabilists*, whose minds disdained to consider the changes of form and structure of organized matter, derived the notion of two opposite species of inflammation—*sthenic* and *asthenic*. Neither is it likely that either the scalpel or the microscope furnished Troxler with the idea, that inflam-

mation is a “tendency to the solution of the organic individuality;” to Gutfeld, that it consists in “a disproportion of fundamental functions;” to Marcus, that it depends on “an alteration of the second moment in the second dimension of the organism.” Burdach, Walter, Seiler, Sprengel, and Dzondi, were less wide astray from the experimental method and the best established opinions, in considering inflammation as “an abnormal augmentation of the organic incitation in the capillary vessels, joined to a change in the plastic power;” though they were not a little too fanciful in seeking the explanation of the phenomena of disease in the laws which regulate the universal powers of nature. The explanation of the phenomena I have just described forms a small part of the anatomical history of inflammation generally considered. Those phenomena, which have been improperly named terminations of the disease, are perhaps those which offer most interest and most difficulty. Besides *resolution*, or the return of the part to its natural state—which constitutes indeed the only true termination—the phenomena which may succeed to these we have been studying are too many and too complex for any of them to be considered as leading directly to a cure. The truth is, the same affection, inflammation, is continued under different forms, which have received particular names, and of which each has been the object of a multitude of works, such as induration, softening, suppuration, ulceration, gangrene. We must now proceed to inquire what changes are brought about in the blood and the products of secretion.

The act of inflammation brings about certain changes in the blood; of these, some are appreciable to our senses, others, though invisible, may nevertheless be demonstrated by reason. Nothing is more common than the alteration termed *buff*, which is shewn at the surface of the clot of blood taken from a vein, under the appearance of a layer of suet. Viscid, soft, and filamentous, at first, it does not become dense and strongly adherent to the cruor until the coagulation of the clot is complete. Considered chemically, the clot is completely dissolved in warm water when it is soft and mucous, incompletely when it is condensed. Water saturated with nitrate or carbonate of potash, or dilute acetic acid, dissolves the buff, but the action of concentrated mineral oxides augments its density. The result of these experiments would imply that the buff is composed of fibrin and albumen, or fibrin and very albuminous serum. There are certain circumstances which favour the formation of the clot upon the blood of individuals who are plethoric or attacked with inflamma-

tion: 1st, a sufficiently large opening in the vein; 2d, a projecting jet of blood; 3d, the form of the recipient, which should not be wide, but deep; 4th, the temperature of the vessel in which it is received, and which should not be cold; 5th, repose after its fall into the recipient. Gendrin has prevented the formation by letting flow into the vessel at the same time with the blood a small stream of a solution of caustic potash: it is equally prevented by letting the blood flow from a height, drop by drop. He has also observed that blood taken at the same time from both arms is identical, though the inflammation may affect only one side; that if we perform two bleedings with an interval of ten or fifteen minutes, the blood of the first presents buff, that of the second does not; but if we bleed a third time, some hours afterwards, the blood is again buffed; that when a buffy bleeding is interrupted by syncope, the blood flowing after the syncope shews no buff. He showed further, that the buff is not the only change in inflammatory blood, but that the clot is denser and smaller, showing a greater contractility in its elements; that in inflammatory blood the serum is more viscous and less coloured than in healthy blood, and that it contains almost a double proportion of albumen; that its density and buff are in relation with the different periods of inflammation. Whatever may be the cause which increases the quantity of fibrin and albumen in inflammatory blood, and whatever may be the mechanism by which the augmentation of plasticity and of fibrin occasions the absence of colouring matter in a part of the clot, it is, I believe, true that these changes are brought about under the influence of some vital action.

It may be as well here to say a few words on the vitality of the blood. The fluids, like the solids, possess a power of resisting causes which tend to their destruction. This is proved by Hunter's experiments upon the egg and the blood—experiments in which these fluids, in an unaltered state, have resisted congelation for a longer time than those whose physiological properties had been destroyed by a previous congelation. He also shewed that the coagulation of the blood did not depend upon the contact of air, since it coagulates sooner in space, nor from rest alone, since it sometimes coagulates while circulating. Something else must, therefore, be found to explain it—its vitality. Physiological experiments shew that poisons which destroy the vitality of the solids, however small the quantity employed, produce almost instantaneous changes in the composition of blood, either coagulating or destroying it. Fontana has seen

the whole of the blood in a sparrow blackened and coagulated by a single drop of the venom of a viper. Tiedemann and Gmelin, and Orfila, show that in poisoning with mercury the blood remains fluid; others have shown that it is blackened and very fluid in poisoning by arsenic (Jäger); that in poisoning by prussic acid it is changed into a black, viscous, gummy matter, of the consistency of oil (Itrici); and that the electric fluid, at the same time that it destroys muscular irritability, liquefies the blood, and prevents coagulation. The microscopic observations of Home, Brand, Prevost and Dumas, which demonstrate not only the particular form, but also the intrinsic movements of globules during coagulation, also induce an impression of their vitality. In fact, when we examine, through a microscope which enlarges a hundred and fifty times, blood recently taken from a vein, we see a kind of gyrating movement of the whole mass. The phenomenon lasts for some time after the blood is removed, then it coagulates, and another sort of movement is described, perceived by Heidmann. We see a kind of reticular tissue, which moves for many minutes, and which resembles feeble muscular contractions. Dilute muriatic acid increases this movement, whilst stronger acids immediately destroy it. Whether, as some have done, we should place the blood on the same line with infusory animals, may be very questionable. If, says Edwards, the electric spark is passed through a drop of blood, we shall see the molecules which it contains take at once a strawberry-like arrangement, which indicates the partial separation of the elementary globules of which it is formed. If we make the same experiment on a fluid containing infusory spermatic animalcules, we shall observe the same effect; at the same moment these beings will lose the spontaneous movement with which they were endowed. Looking at these facts, we are astonished at the insignificant part which the blood has been disposed to play, and might be tempted to attribute to it a greater measure of vitality than it really possesses. And if such be the nature of the blood in the natural order, how much more remarkable may its qualities be in the pathological state. But if, on the one hand, proofs are presented in support of the belief of an exalted vitality of the blood under inflammatory action, there are others which demonstrate the alteration of this fluid under opposite circumstances, and when the blood is otherwise modified. The ancients knew that in malignant fevers the clot is absolutely diffident. Dr. Stocker established the same fact in epidemic typhus in Dublin; Gendrin has shewn the septic qualities of the blood in

putrid fevers, and also that blood taken from variolous patients had not only an inflammatory character, but also deleterious qualities, so much so that, when injected into the veins of animals, it excited in them mortal inflammations.

In the condition of health all the tissues are bathed with a fluid in the state of vapour. We may ascertain its presence by making an incision into the cellular or other tissue. We can also ascertain the nature of this fluid by the following experiment. Produce artificial œdema, by making a circular pressure around a limb without including the principal artery. After some hours the limb is much infiltrated by a serous fluid, which does not spontaneously coagulate, but may be easily coagulated by alcohol or a weak acid. This fluid is evidently an albuminous serum, like that of œdema produced by disease, or the serum of the blood. Immerse the tissue in alcohol or boiling water, and we obtain whitish yellow jelly, most abundant where the cellular tissue is most lax. That which is most important to establish is, that a similar coagulation is not spontaneous; therefore the infiltrated fluid does not contain fibrin—for the faculty of spontaneous coagulation is the most marked characteristic of fibrin. Examined by means of the microscope, when perfectly fluid, no globules are apparent; when half dried, some irregular globules are apparent, smaller than those of the blood; in fact, like those of dried serum. The character of the fluids ordinarily secreted in the absence of inflammation it is important to bear in mind. When inflammation exists even in its congestive state, the quantity of this fluid is usually increased; but as soon as the inflammation has acquired a certain intensity, a certain portion of this matter undergoes a jelly-like coagulation, extending to the limits of the inflammation; a certain portion remains fluid. If the inflammation be more intense, the infiltrated fluid, of a darkish red colour, is spontaneously coagulated. It is then sanguinolent, or even pure blood at the centre, and around the circumference the gelatinous infiltration prevails. Still, further, it becomes serous, yellowish, or even almost colourless. Examined through the microscope, we see in the bloody and coagulated mass globules of blood deprived of their colouring matter, which is separated from them almost as soon as they escape from the vessel (Gendrin.) At the limits of this coloured matter these molecules are more rare. There are some cases in which, for the purpose of examination, we may collect a sufficient quantity of the fluids produced by inflammation, before suppuration is established: this is

best done in inflammation of arterics, whose cavity is a sort of recipient for them. Barruel analysed the coagulable substance which is exhaled at the exterior, in the cavity, and in the thickness of the parietes of an artery tied with a ligature. This white soft matter, which presented a sort of fibrinous texture, is not dissolved in cold water. Subjected to boiling water it was not dissolved, but it became solid, and contracted a little upon itself; then, broken into pieces, a distinctly fibrinous structure was shown. Plunged into a warm solution of caustic potash, the greater part was dissolved, but less promptly than that of thickened albumen, a little more rapidly than fibrin. If we follow the formation of this coagulable substance from its origin, we discover that it is primitively formed of an albuminous serosity, which becomes more and more fibrinous and spontaneously coagulable as the inflammation is more intense.

Whatever may be the place where this lymph is deposited, whether on the surface of organs, in their substance or their parenchyma, the product and the effects are the same. In one and the other this lymph is coagulated, thickens, changes its nature, and in the end may become organized, and vitally connected with the tissues with which it is in contact. No doubt this is the source of many organic transformations. It may be a question whether transformations do not differ from degenerations in this—that in the former the exuded matter is susceptible of becoming organized, while in degenerations the substance which forms them can never enter into organic relations with the ancient tissue, and cannot become the germ of new tissues similar to the old. This lymph is soft, viscous, filamentous, and pulpy: in chemical composition it seems to be formed in great part of fibrin. Moore, I apprehend, was quite wrong in maintaining that it had never been fluid. How could it escape from the vessels in the form of membranes? Its colour is white, yellow, or greyish: its thickness upon the surface of inflamed organs varies from the tenth of a line to an inch. It is sometimes deposited between many layers, between which a serous fluid is occasionally found. In other circumstances, independently of the coagulating lymph, a certain quantity of serum is found in certain dropsies. This we know, by chemical analysis, that the serous fluid becomes more rich in plastic and organizable matter in proportion to the progress of the inflammation; receiving, of course, from the blood a greater quantity of albumen and fibrin. As to its appearance, it is at first amorphous; much as we see it in the bulky coat in inflammation. It does not,

however, remain long in this state, but soon acquires a flocculent appearance, is filamentous or reticulated, and porous; something like the *membrana caduca* of the uterus. A little later it exhibits in its substance spots of blood, then streaks, which have the appearance of vascular ramifications, and at last these streaks are transformed into true canals, containing blood, and insculcating with the old vessels of the organ on which the exudation takes place. This lymph is the medium of union in those wounds which heal without suppuration, and between inflamed parts. It is through its agency that the pleura pulmonalis unites with the pleura costalis, the intestines to the peritoneum, the Fallopian tubes to the ovaries, &c. Serous membranes, more frequently than any others, are the seat of this exudation. After the serous membranes come the mucous, and next, probably, the internal tunics of vessels. In the mucous surfaces the lymph forms cylindrical conerctions, which take the form of the tubes in which they are found; such are the macaroni-like tubes sometimes spit up from the bronchiæ. All these layers of lymph upon surfaces constitute, what are termed, *false membranes*, the nature of which I shall now point out to you. We may admit four states or periods in the development of false membrane: first, the period of formation; second, that of increase; third, that of organization; fourth, that of maturation into cellular tissue. In the first period, twenty-four hours after we inflame a serous membrane, we find it much injected, and upon its surface an extremely thin and tender layer of a pulpy villous substance, like so much gauze or cobweb, which the slightest friction would remove: this thin pellicle has one surface applied upon the serous tunic, the other free, villous, and sometimes mammillated. The second period begins as soon as the exudation has a membranous appearance, and is characterized by increase of thickness and density of the false membrane. We sometimes find inflamed organs which exhibit the lymph in different degrees of consistency of aspect, and even of organization. I have seen on the same lung, in consequence of inflammation of the pleura, the layer of lymph at one point scarcely adherent to the surface; in another, strongly adherent; in a third, beautifully reticular. The third period is characterized by the density and by the presence of blood-vessels. Stoll believed they might be organized in twelve days, sometimes even in eight or nine, from the invasion of the disease. Home said vessels might appear in them in twenty-four hours. The concretion of albumen is not owing to the heat of the part, because for this purpose

a temperature of 160° is required; it is a vital act, more easily observed than comprehended. In the fourth period it undergoes a change in appearance, becomes thinner, and daily more like cellular tissue; and before long presents diaphanous laminae, extremely thin, soft, and arranged like those of cellular tissue. There is not only identity of appearance with cellular tissue, but also identity of use, and even of diseases; and it never contains fatty matter.

Another change, to which tissues affected with inflammation are liable, is an increase of density and of cohesion. This change is more commonly a consequence of slow or chronic than acute inflammation. It is produced in the following way:—The serous fluid which is exhaled from the blood-vessels in a state of inflammation becomes more and more charged with fibro albuminous matter; it distends the cellular tissue, becomes concrete under the influence of inflammatory action, and may become organized. The cells, therefore, instead of containing a gaseous, or fluid matter, are distended by this concrete or organized matter, and *induration*, with or without sensible tumefaction and change of colour, is the consequence. Under any circumstance this condition is not soon dissipated: if the matter be still unorganized, we can often act upon it by exciting the absorbents to increased action, by means of stimuli; but, before these are used, inflammatory action should be subdued. If the matter have become organized, our efforts to procure its removal through absorbent action will be useless. The tumefaction will remain, and the new matter may or may not assume certain of the characters of the tissue in which it is developed. It may, on the contrary, be a non-analogous tissue—may continue to increase—may constitute a tumor of varying physical characters. Although the irritation which has produced this state of things has ceased, it often happens that the molecules of matter deposited under its influence continue to be nourished and to live; more blood is necessarily directed to the part, and the vital action is increased. There are cases where an opposite condition is manifested, where the vitality is lessened, where the colour is paler, and where masses of matter seem almost inert; and by these circumstances it is easy to explain the success of opposite modes of treatment.

Another change may be brought about in the texture of an inflamed part, at the same time that the absolute weight and specific gravity of an organ are increased; its cohesion may be diminished; and this constitutes the state of *softening*. Vaguely described by the older anatomists, it has

much occupied the attention of modern observers. There is scarcely any organ in the human body in which the condition has not been demonstrated. The most solid parts cannot resist it; the cornea in ophthalmia, the arteries in arteritis, the bones in certain varieties of white swelling, all suffer. It may present itself in a tissue which is still solid, but which may be ruptured, perforated, or destroyed, with the greatest facility; it may proceed farther, and, instead of a solid, we find only a pulpy mass; or still, further, when this pulp has disappeared, and only *débris* of the original structure remain. This condition may be brought about in a very few days, even in a few hours; the inflammatory action may be either chronic or acute. It is necessary very carefully to discriminate between *induration* and *softening*. In a case of acute pneumonia, the blood by which the bronchial parietes are gorged, by tumefying these parts, may efface the air-passage; no air penetrates, and the consistency of the pulmonary parenchyma seems to be singularly increased; but it is only in appearance; the slightest traction is sufficient to break it down; the finger passes through it easily. Cohesion, therefore, is the test; otherwise we may confound increase of density with increase of consistency.

I shall now proceed to give you a summary of what is best established upon this very interesting and highly important subject. We have clear demonstrative evidence that by exciting pain upon any part of the body supplied with blood-vessels, unless the stimulus be too intense, or possess peculiar chemical properties, the capillary vessels at the irritated point undergo immediate contraction; the blood contained in those vessels is pressed forward more rapidly, and the part upon which the irritation is applied is at that moment paler than in its natural condition. To this state succeeds another, similar to that of blushing, violent exercise, and so on: the previously contracted capillary vessels present an opposite condition, their contractile power is exhausted, and they become considerably dilated; and those which did not before present a sufficient diameter to admit the red globules of blood, now admit them freely; but this altered condition of the vessels is accompanied by an altered condition of the blood; instead of moving rapidly, as it did during the contraction of the capillaries, a decreasing velocity soon becomes apparent, the movement of the blood becomes slower and slower, the dilatation of the vessels increases, and after a short time stagnation is complete. This state of *congestion* may be dissipated (if the source of irritation ceases) by the

vessels themselves becoming sufficiently recruited to contract anew, and with sufficient force to cause the blood again to circulate; or, in the absence of that power, by the application of a different or more energetic stimulus. Thus, a frog's web being soaked in a solution of muriate of soda, the vessels being dilated, the blood retarded, and losing its globular appearance, the state was completely dissipated by the application of alcohol, the vessels contracted anew, the blood circulated, resumed its globular appearance and its red colour. This condition may be diminished by the application of cold, acetate of lead, and similar topics: these agents lessen the vascular action by producing contraction: this is evident by the paleness they produce; astringent tonics may succeed if the former fail. That such is the *modus operandi* of cold is shewn by the experiments of Poisseuille: he has kept tadpoles at a temperature of 77°; into the water in which they were kept he has put a piece of ice; the circulation in the capillaries became slower, the globules of blood were elongated and became pyriform in attempting to pass along the vessels, and assumed their primitive condition as soon as they had traversed the channels thus narrowed. If left longer in water, the temperature of which was thus reduced to one or two degrees Reaumur, the circulation ceased in the greater number of the capillaries. The same experiment was repeated on the bladder of very young field-mice; the contact of ice, for only a few minutes, produced a complete and permanent abolition of the circulation. The local abstraction of blood, by emptying or relieving the tension of the vessels, gives them time to contract: this may be well shown by a familiar case. A child is seen with a suffused face, red and irritable conjunctiva, intolerance of light; the head is heavy; he sneezes; his frontal veins are dilated; his nose bleeds; and he is cured. The hæmorrhage does not recur; an erysipelas of the face, ophthalmia, inflammation of the brain, or some such visitation, is the consequence. Such are the principles of treatment of congestion, whether it end there, or whether it be the first stage of inflammation. Indeed, between this condition and inflammation, it is very difficult, if not impossible, to set a broad line of demarcation. Before we proceed further it may be as well to consider, shortly, how this state of dilatation of the capillary vessels is brought about. Some persons believe in the existence of an "active dilatation" of these vessels, as a consequence of which blood is "solicited" or "aspired" into them; in this way referring all action in the matter to the capillaries. To this doctrine I cannot

assent, because I know no analogy in support of it. That dilatation should succeed to contraction is perfectly intelligible, for it is only an exaggeration of the laws of vital action—a state of activity and repose—contraction and relaxation being invariable consecutive conditions of the organs of the body; but that repose, or *that* dilatation, cannot, I apprehend, produce a diameter greater than is natural to those vessels. Another cause of this condition must, therefore, be sought, and I see no difficulty in accepting, as *that* cause, the increased action excited in the vessels around the part. The contractility excited in the affected capillaries being exhausted, a period of repose follows; the surrounding vessels continue to act vigorously, propelling blood in all directions upon the irritated point: advantage is taken of their exhaustion; they offer no resistance, become inordinately dilated, and unable to contract with sufficient energy to expel their contents. I think the best distinction which can be drawn between congestion and inflammation is to hold that where stagnation is incomplete—where it is not more than can be easily dissipated, and no exhalation occurs—it is a state of congestion; and that, when stagnation is complete, inflammation is developed. Pass this period, stagnation being complete, the tendency to coagulation of the blood is more decided; the globules are, as it were, glued together—their colour is darker or browner; the ordinary secretions are momentarily interrupted: soon an exhalation takes place, the fluid is more or less perfectly serous or sanguineous; soon we shall observe a softening of the tissues, produced by this infiltration, and a gradual decoloration of the stagnated blood. This infiltrated serous fluid, more or less charged with fibrin, undergoes remarkable changes: when exhaled upon certain inflamed surfaces its fibrin is coagulated, and constitutes false membranes; when exhaled into the substance of tissues, the fibrin may still be separated in the same manner, and often constitutes the nucleus of tumors. When this infiltration into the interstices of vessels is effected, it adds to the irritation which produced the congestion; it increases the sensibility; so that, for a simple, stinging heat, we see a tense, dragging pain substituted.

When inflammation has once fairly set in, the blood is fairly stagnated, coagulated, and when topical applications, such as we alluded to in speaking of congestion, are insufficient again to set it in motion,—when the surrounding tissues are infiltrated, and when the irritation has gradually extended to the whole system, producing sympathetic fever—when increased general vascular action tends to increase

the local evil—other modes of treatment must be resorted to.

The first object of care is to remove, if practicable, the cause of local irritation, as a means of lessening the afflux of fluids. We must then attend to a *second* source of irritation, which is the pain occasioned by the distension of the tissues, by the arrival of an increased quantity of blood: this may be so great as to distend the vessels to twice or three times their natural size: this new ingress may be lessened by cold, by emollients, by sedatives; but they may be quite insufficient, and local and general abstraction of blood may be necessary, in quantity dependent upon the intensity of the symptoms. And as I have already shown you that the blood in this condition of the economy undergoes considerable change in its quality, becoming a greater excitant, it requires tempering: this is to be done by the exhibition of diluent fluids, by which it is diluted, the proportion of serum being increased. If inflammatory action be not very intense, the use of these means, which constitutes the antiphlogistic plan of treatment, may be sufficient to lessen the afflux of blood, to restore the capillary circulation to its natural condition, and to dissipate the local disturbance. But when the inflammatory action is more intense, or has existed longer, although the afflux of fluids may be moderated by the means indicated, yet the gorged capillaries are unable to resume their wonted character; it may be necessary to resort to a tonic or even a stimulating plan, to give them the energy they have lost; following out, in fact, the plan which the microscopic experiments, to which we have alluded, by Wilson Philip, Hastings, and Kaltenbrunner, have shown to be capable of exciting contraction, in these distended or exhausted vessels. Again, the morbid products of secretion may require still further local stimulation to secure their removal; they may require the energetic and sustained employment of the counter-irritant treatment. There are cases, however, in which all these means may fail in procuring the absorption of a morbid product; the mass may become organized, and assume more or less of the character of the adjoining tissue, or it may constitute a non-analogous tissue. But in employing stimulants locally, for the purpose of dissipating the induration caused by the exudation of fibro-albuminous matter, great caution is necessary; there may still be an afflux of blood to the part: then the antiphlogistic method should be employed. There are other cases, where the quantity of blood directed upon the part, as well as its general vitality, is lessened: these are the cases for the use of the revulsive

methods of treatment: this precept is not simply the result of theory; the theory justifies a practice which has no doubt been much abused, but has also been, unquestionably, very successful. Bear in mind, therefore, that much prudence is necessary in the use of this method; never lose sight of the circumstance, that though it may restore an indurated tissue to a healthy condition, it may also increase the irritation. By the side of those rational methods of treating induration, another and empirical one may be placed. We should endeavour to discover some substances which, mixed with the blood, would exercise a discentient power. Mercury will often cause the absorption of exostoses; mercury and iodine seem now and then to exercise similar power over induration seated in the soft parts.

## LECTURES

ON

## THE PHYSIOLOGY OF THE STOMACH,

*Being the Gulstonian Lectures for 1839;*

*delivered at the Royal College of Physicians in London,*

By R. B. TODD, M.D. F.R.S.

Fellow and Censor of the College; and Professor of Physiology, and of General and Morbid Anatomy, in King's College, London.

## LECTURE I.

THE process of digestion is not only, of all the animal functions, the most widely spread in the scale of animals, but it is likewise the most complicated in the higher classes: so much so, that the full consideration of any one of the sub-processes of which the function consists would afford ample scope for physiological inquiry and research. There is one part of this process, however, which is constant in its existence, from the most simple creature up to that which possesses the most elaborate digestive apparatus. I allude to that peculiar reduction of the food which takes place in the stomach of the higher animals, and which is obviously the result of a duration, for a certain period, of the alimentary substances in that cavity. This part of the process, commonly called chymification, or which may be properly denominated "stomach digestion," occurs in all animals in whom a true digestive function exists—that is to say, in whom the food undergoes a certain elaboration within the interior of the body, before it can be applied to the purposes of supplying the waste of the solids and fluids.

Let us take, for example, an animal at the bottom of the scale—the fresh-water polype, *Hydra viridis*. This creature, so perfectly simple in its structure, without any distinction of parts—its entire body consisting merely of a sac with a single orifice, which serves both as inlet and outlet—not only has a wonderful power of seizing with its tentacles the bodies of animals more highly organized than itself, and of introducing them into the interior of the cavity into which its body is hollowed, but the interior of that cavity exerts a destructive influence upon the substances contained in it; so that when these substances are again expelled through the same orifice, they have lost their form: they appear dissolved upon the surface, to a greater or less depth, and cannot be recognized as the same substances which found their way into the interior of the creature. According to Trembley—the discoverer and historian of this interesting class—animals introduced alive into the interior of a polype, always die within a quarter of an hour. The food thus swallowed distends the little body of the polype, so that the walls of its cavity or stomach, as it may be called, are rendered sufficiently transparent to enable the observer to watch the process as it goes on within. At first, Trembley tells us, the animals can be distinctly seen unaltered in the body of the polype, but after a time, we find that they gradually lose their form, until at length they become so altered as to be no longer recognizable: they become reduced, as he says, to a "*bouillie*," which contains fragments of various sizes, of the more solid parts of the animals, which have been but slightly or not at all acted upon. The greatest part of this *débris* is subsequently expelled from the body of the animal, through the same opening as that by which the food was introduced; nothing remaining but a fluid which may be supposed to consist partly of the dissolved nutritious materials, to be appropriated to the nourishment of the animal, and partly of some yet remaining excrementitious matter, the expulsion of which, from its small quantity and fluid nature, Trembley says, is not easily observed.

Such is a brief account of the digestive process in these very simple creatures, and it will serve to illustrate the essential part of the process in all higher animals. If the function experiences any degree of complication in other classes, that complication results from the addition of other accessory processes, either previous or subsequent to the solution of the food in the stomach: thus, while we observe the greatest variations in the mode of prehension of the food—its mastication, the de-

gree to which it is mixed with fluids or macerated, before its introduction into the cavity, and the extent of surface with which it is brought into contact after it has, in a very altered form, left that cavity, and previous to the expulsion of the excrementitious part—we nevertheless find, that in every instance the presence of a cavity into which the aliment is very early introduced, and in which it, after a longer or shorter time, becomes completely disintegrated, is a never-failing characteristic of the process of digestion. This fact, which is abundantly proved by the comparative anatomy of the alimentary canal, would alone invest the process of chymification or stomach digestion with the highest degree of importance in a physiological point of view; but when we take into account that in man and those higher animals in whom we can observe the process, the whole system sympathizes, in the most marked manner, with this particular function—that while the food is being thus acted upon in the stomach, most of the other functions are in a state of excitement; the circulation and respiration are accelerated, and a general febrile state is induced, which continues, with more or less of intensity, till the process is completed; I say, when we take into consideration the influence which this process exerts upon the other great functions of the body, it must be obvious that the physiology of stomach digestion ought to afford an interesting and important subject of inquiry to the practical physician, as well as to the physiologist. If this process, in its normal state, gives rise to so much constitutional disturbance, how much greater disturbance will there be should any thing interfere with or impede the healthy and natural performance of it? How necessary, then, is it that the physician should be well acquainted with all those conditions which favour the process, as well as those which retard it; and how important that his knowledge of the function should provide him with expedients to which he can have recourse when necessary!

I propose, then, to consider in the present and two following lectures—the physiology of the stomach. I shall, first, examine the anatomical characters of that organ in the vertebrated classes, and more particularly in the human subject; secondly, I shall describe the minute structure of its internal membrane; and lastly, I shall endeavour to lay before you the present state of our knowledge respecting the nature and essence of the function of the stomach.

Physiologically considered, the stomach presents a perfect uniformity as regards its general anatomical characters, in all

the vertebrata. It may be defined to be a sac, provided with an external muscular investment, and lined by a mucous membrane, from which, under certain circumstances, a secretion is copiously poured out of decided chemical properties, affording an acid reaction, and, when kept at a certain temperature, capable of exerting a solvent power on alimentary substances. But the limits of the stomach, as that term is applied in the language of the anatomist, are by no means so precise. Speaking anatomically, we consider the stomach to be a bag, either simple or divided into several chambers or cavities, situated at the commencement of the digestive canal, and in which the food is deposited immediately after it has been swallowed, either for maceration or for solution. And in every case we shall find a distinct line of demarcation existing between the physiological and the anatomical stomach, although in some instances they may both form one and the same bag.

The human stomach may be taken as an example of the simplest condition of this organ; it must be regarded as entirely, or almost so, a physiological stomach; for it answers completely to the definition I have already given. It is a simple cavity, and seems to result from a dilatation of one wall of the œsophagus. Its formation may be accounted for in this way: the œsophagus, immediately it has passed through the diaphragm, turns abruptly to the right side, inclining a little downwards; but its left wall bulges out considerably towards the spleen, forming the great cul-de-sac, the great curvature, and the lesser cul-de-sac, before it again falls into its original relation to the right wall, and restores the primitive cylindrical form of the alimentary tube. The dotted line in this figure will serve to illustrate the description of the mode of formation of the stomach:—

The human stomach has the shape of a cone, the basis of which corresponds to the left or splenic extremity, whence it gradually tapers to the pyloric extremity, which forms the apex of the cone. The orifice of communication with the œsophagus (*the cardiac orifice*) is situated at the line of junction of the left and middle thirds of the stomach, that portion which lies to the left of this orifice forming what is called the *great cul-de-sac*, a part whose development is of considerable physiological importance. In the adult stomach this part has reached its maximum of development; but at the earlier periods of extra-uterine life it is scarcely at all developed; and even in the infant at birth, and during childhood, this portion is of comparatively very small size; so that, in the latter case, the œsophagus is inserted near the left extremity of the stomach, and the whole of this organ has a more decidedly conical form than at the adult period. Schultze has particularly pointed out this difference of shape in the human stomach at these two periods, as serving to account for the comparative facility with which the act of vomiting is accomplished at the former period. In common with others of the abdominal organs, this viscus acquires a serous investment from the peritoneum, which, however, is so loosely applied to it opposite the curvatures, as to leave a space in each of those situations in which run the arteries that supply the stomach with blood. It is likewise invested by a muscular coat, composed, like the muscular tunic of the whole intestinal canal, of two planes of fibres—an external one, consisting partly of longitudinal, partly of oblique fibres; and an internal one, formed of circular fibres. The muscular coat is principally developed upon the right third of the stomach, or that segment of it which anatomists designate the pyloric portion; and the circular fibres acquire their maximum of development around the pyloric orifice, to which they perform the office of a sphincter. But it is from the internal membrane that we can form the most correct judgment of the physiological character of the organ: this membrane belongs to the class of mucous membranes; it is soft, thick, highly vascular, and in the natural state always moistened upon its surface by a more or less thick layer of mucus, which may be readily washed off by a stream of water directed upon it, or scraped off with the back of a scalpel. This membrane differs very obviously from the mucous membrane of the œsophagus, not only in its softer texture and more pinkish hue, but likewise in the absence of any epithelium upon it visible to the naked eye. Although I shall presently show, when I come to speak of the minute

anatomy of this membrane, that it is not devoid of epithelium, yet the epithelium of the œsophagus may be said to cease abruptly at the confines of the cardia, its termination being indicated by a jagged margin, which extends round the whole circumference of the orifice. I have satisfied myself that this thick epithelium of the œsophagus does not extend into the stomach in the human subject, and therefore the line of its cessation may be regarded as that whence the stomach may be said to commence. The non-existence of an epithelium obvious to the naked eye is the distinctive character of the physiological stomach; and, on the other hand, the presence of a thick epithelium indicates a different office from that which must be admitted to belong to the physiological stomach.

It is not uninteresting to notice, that the human stomach sometimes presents a constriction corresponding to the line of union of its middle and pyloric third, thus giving rise to more or less of an hour-glass appearance in the viscus. It is along this line, it will be remembered, that the muscular tunic belonging to the pyloric portion of the stomach acquires an increase of thickness; and the constriction is in some cases owing to a temporary contraction of the band of fibres covering that portion, when it will, of course, disappear after death under the influence of any distending force; or, at other times, it is occasioned by some permanent and probably congenital contraction: in such cases the constriction cannot be removed by distension of the stomach with air or liquids, and it will remain even after the stomach, when distended with air, has been dried. The theory of Sir Everard Home, that this division into two portions by a constriction is a regular and normal result of the part which the stomach plays in digestion, is devoid of foundation, and has been contradicted by the experience of every observer since his time; and still less grounds are there for his supposition that the cardiac and pyloric portions performed separate and distinct offices. The truth is, that to find during digestion a constriction in the stomach of an animal in which such constriction does not naturally exist, is the exception and not the rule; and that even when the constriction does occur, it in no degree interferes with the free passage which exists between the two portions.

Although this subdivision into two distinct portions is not naturally manifest in the human stomach, it is remarkable that, in the gradual departure which we observe among mammalia from the simple physiological stomach, such as the human stomach is, we shall find a progressive

advance towards the complete separation of the viscus into a right or pyloric portion, which always retains the characters of the physiological stomach, and a left or cardiac portion, which, as it becomes more completely separated, performs more exactly the office of a simple receiving and macerating cavity.

The first step in this change consists in the extension of the œsophageal epithelium into the cavity of the stomach, so as to cover a portion of its mucous membrane for a little way beyond the cardiac orifice. In the purely carnivorous stomachs this is the case, as in those of the cats and dogs. Although the epithelium passes into the stomach, and thus encroaches upon the secreting membrane, it does so to a very slight degree, and therefore the stomachs of the carnivora differ in no essential character from the human. In external form they are more simple, inasmuch as the great cul-de-sac is less developed. In the hog tribe another stage is passed over in the further continuation of the epithelium into the cardiac portion, although still for a very short distance: here, however, the stomach is divided by a slight but permanent constriction, leaving two-thirds to the cardiac portion, and one-third to the pyloric. The former, however, it is evident, from its being but to a very small extent lined with epithelium, still retains in great part the physiological character. In the pecari and the hippopotamus there are two blind pouches from the cardiac portion. In the Solipeds—the horse, ass, &c.—there is not only a slight constriction visible externally, and corresponding to the limits of the cardiac and pyloric portions, but the whole of the cardiac portion is lined by the prolonged œsophageal epithelium, so that on laying open the cavity of the stomach the two portions are at once distinguished by the difference in the character of their lining membranes. In the horse it is well known that the bots or larvæ of the *Æstrus bovis* of Linnæus, are developed in this part of the stomach. The insect lays its eggs in the shoulders and forelegs of the horse, whence the larvæ when hatched can be licked off and swallowed. They are found during spring in great numbers, adhering by little hooks at the anterior extremities of their bodies to the internal membrane of the stomach, from which they cannot be detached by force, without tearing off a portion of the epithelium with them. The cardiac portion, then, of the horse's stomach must be regarded as merely a macerating cavity; the physiological stomach being that portion which is situated to the right of the constriction, and belongs to the pylorus. The stomach of Rodentia, as the rabbit,

the rat, resembles considerably that of the Solipeds: like the latter, it is divided by a constriction visible externally into a cardiac and a pyloric portion, and the former is lined by epithelium: the cardiac portion in many is of considerable size, and in some genera experiences a subdivision by another constriction into two portions. The beaver, in this order of mammalia, presents the remarkable peculiarity of the addition of a special glandular apparatus to the cardiac portion, situated immediately to the right of the opening of the œsophagus, composed, according to Sir Everard Home, of a series of branched follicles, which pour their secretion into the gastric cavity. These follicles are collected into three rows, situated between the muscular and mucous coats, upon the latter of which they open by large and patulous orifices. A similar arrangement exists in the stomach of the wombat (*Phascalomys didelphis ursina*, Shaw,) an animal from New Holland, one of the Marsupialia, which resembles the beaver in other characters likewise; and in an animal indigenous to this country, the dormouse (*Myoxus avellanarius*), a glandular apparatus of the same kind is found, but somewhat differently placed. In this animal the glandular apparatus is situated in a dilated portion of the œsophagus, just before it enters the stomach: in structure, however, it precisely resembles those described in the beaver and wombat. These glands, as it appears to me, result from a higher degree of development of a structure which exists in a simple condition in, I believe, all mammalia, certainly in man, and the higher quadrupeds which more commonly come under anatomical examination. They belong to the œsophagus more than to the stomach, and do not in general extend into the stomach unless the œsophageal epithelium does. In such cases, therefore, they would be limited to the cardiac portion, and are generally found most numerous along the upper curvature, or to the right of the œsophagus. The great development of these glands in the three animals I have mentioned appears to have reference to the arid nature of their food, which consists of the bark of trees, hazelnuts, corn, fallen acorns, &c., and which probably requires to be moistened to a greater degree than could be effected by the more simple glandular apparatus of the stomach. But whether the chemical constitution of the secretion differs in any way from that of the ordinary mucous fluids poured out upon the surface of the œsophagus, I have not had any means of ascertaining.

So far as we have proceeded in our examination it is manifest that the subdivi-

FIG. 1.

sion of the stomach, anatomically considered, becomes progressively more complete, into a cardiac portion and a pyloric portion, the latter of which, from the absence of an epithelium manifest to the naked eye, as well as from the characters of its membrane, of which I shall presently speak more fully, is always concerned in the true physiological action of the stomach. In all these instances which I have mentioned, so free is the communication between the cardiac and pyloric portions, that the stomach may still be said to consist of but a single cavity, although the two portions are physiologically as distinct as if they were separated by a perfect septum.

The Cetacea and Ruminantia are those orders of mammalia which possess the stomach in its most complicated condition. In the latter of these orders, the ruminants, the cardiac portion undergoes subdivision by means of constrictions, which

give rise to the projection of more or less perfect septa into its interior, by which the various compartments are separated from each other; but as these septa are never complete, a communication always exists between the several compartments with each other. In the Cetacea, however, on the other hand, the multiplication of compartments seems to be connected chiefly with the pyloric portion, or true physiological stomach, as far as we can judge from our present imperfect data. In the porpoise we find, according to the description of Hunter, five separate compartments, of which only one, the first, communicates immediately with the œsophagus, and is directly continuous with it. This is a large bag, constituting the splenic end of the stomach (*a*, fig. 1), and therefore corresponding to the cardiac portion; its mucous membrane is lined throughout by the continuation of the œsophageal epithelium. The second compartment (*b*, fig. 1), situate to the

right of the first, communicates with it, but not with the œsophagus. The orifice of communication between the first two stomachs is surrounded by a number of large irregular projections, which seem calculated to impede, if not to prevent, the passage of substances, save only such as are of small size. From the fact that the epithelium is not continued beyond the confines of the first stomach, and from the account which has been given by Sir David Brewster of his microscopic examination of the lining membrane (the only one, so far as I know, which has yet been made), I am led to believe that the second stomach is a true physiological one, and that its mucous membrane is capable of pouring out the characteristic secretion. And the same office would seem to be that of the third and fourth stomachs, the former of which, as described by Hunter, is the smallest of all its compartments, and seems to be a sort of offset from the second, and, in my judgment, may more properly be considered a part of the second; it is not visible externally. The fourth stomach (*c*, fig. 1) is much elongated, and has acquired the cylindrical or intestine-like form. It terminates in a dilated oval cavity (*d*, fig. 1) which Mr. Hunter describes as the fifth stomach, but which his able commentator, Professor Owen, regards as the dilated duodenum, since the gall-ducts terminate in it.

Mr. Hunter considered the second stomach of the porpoise to be its true digesting cavity; and Sir Everard Home thought that the fourth stomach performed that function. Until a more complete examination has been made by competent persons of the structure of the mucous membrane by the microscope, we can arrive at no positive conclusion respecting the functions of these compartments; but I feel strongly disposed to believe, from the cessation of the œsophageal epithelium at the commencement of the second stomach, and from the position of the second, third, and fourth stomachs being on the pyloric side of the first, that all three will be found to be true digestive cavities.

If this opinion be confirmed, a step will have been made towards the solution of what has long been considered an anomaly—namely, that the predaceous and carnivorous Cetacea, such as the porpoise, the common dolphin, the hyperoodon, should possess stomachs of so much complexity. In general, the variations in the complications of the stomach would appear to be influenced by the nature of the food; and those animals whose food is most difficult of assimilation, extensive vegetable feeders especially, have the most

complicated stomachs—the complication arising not so much from an increase in the true digesting surface, as from the enlargement of the simple recipient and macerating cavities. The purely carnivorous animal, on the other hand, has a simple stomach, which is wholly a physiological one—wholly a true digesting surface. The reverse is the case with the zoophagous cetacean; his stomach is extremely complicated, and contains, undoubtedly, a macerating cavity; so that even if we can succeed in proving that the last three cavities are true digesting stomachs (fig. 1), the anomaly would not be completely removed, for it may still be asked why should a carnivorous whale require a greater extent of digestive surface, and the super-addition of a macerating cavity, when the simplest form of true stomach is sufficient for the lion or the tiger? But the difficulty is increased by referring to the stomach of the herbivorous cetaceans; the dugong, for example. The stomach resembles that of the pecari or hippopotamus, which differs from the stomach of the hog only in the addition of a couple of cœcal pouches to it.

[Since this lecture was delivered I have had the opportunity of carefully examining the stomach of a porpoise, which was brought to King's College in the summer, with reference to determining the function of each of its cavities. The result of my examination has been completely confirmatory of the opinion stated in the lecture, namely, that not only the second and fourth stomachs afford true digestive surfaces, as surmised by Hunter and Home, but the third stomach likewise. I found on the mucous membrane of each of these cavities microscopic characters, which will be detailed in a subsequent lecture, abundantly sufficient not only to prove the membrane to have the mechanism for secretion, but to establish the exact similarity of its structure with that of the mucous membrane of the carnivorous stomach. The dilated oval cavity, which Hunter describes as the fifth stomach, but which Owen regards as the duodenum, I am led by this examination to consider a portion of the stomach; the structure of its mucous membrane closely resembles that of the second stomach, which all physiologists are agreed in regarding as a true digestive cavity.]

## ON SYPHILIS.

BY HERBERT MAYO, F.R.S.

Senior Surgeon to Middlesex Hospital.

[Continued from page 247.]

[For the London Medical Gazette.]

*Treatment of chancre—non-mercurial plan—Reasons for the use of mercury—Directions for a mercurial course—Accidents of a mercurial course—Difficulty of affecting the system—Dysentery—Hydrargyria—Ptyalism—Mercurial phagedæna—Excitement of the nervous system—Erethismus.*

So much space having been occupied in the attempt to arrive at the diagnosis of chancre, I have next to consider its treatment.

The first element in the inquiry is the important fact, determined by the observations of the army surgeons of this country, that every form of venereal disease may be cured without mercury. I have attributed to the late Mr. Rose the principal part in establishing this conclusion. His attention appears to have been drawn towards it by observing the practice pursued by the natives of Portugal in treating syphilis. He had opportunities of ascertaining that several of them, after sores which he had supposed to be venereal, had been cured without mercury, continued in perfect health during a period of two or three years. A few similar instances came under his observation among our own soldiers, when it happened that the use of mercury was interrupted at early periods by the movements of the army, or other causes. "I had often wondered," Mr. Rose continues, "that in not one of these any ill effects ensued; but I could only infer that my opinion of the disease had been erroneous, although, in the cases to which I allude, it had been by no means hastily formed, and the sores had every characteristic of true chancres." Reflection upon these facts, and parallel instances that were communicated to him, led Mr. Rose to determine to make a sufficient trial of the non-mercurial treatment. Accordingly this plan was pursued in all cases of primary venereal sores, as well as in the constitutional symptoms to which they gave rise, that occurred

in a battalion of the Coldstream, consisting of a thousand men, stationed in London, during a period of a year and three-quarters. The result was their uniform recovery, although it was certain from the number affected and so treated, and from the appearance of many of the primary and secondary disorders, that a proportion of these cases must have been true syphilis. It further appeared that secondary diseases by no means constantly followed those sores even which presented the least questionable evidence of a syphilitic origin; and that the constitutional symptoms when they manifested themselves, did not bear a more severe or inveterate character than after the use of mercury.

One important practical inference is immediately deducible from the facts thus verified. The administration of mercury for syphilis may be confidently abandoned in all cases in which, from individual or hereditary peculiarity, its use is likely to injure the constitution, or in which, in former or present experience, it has proved prejudicial, or in which a reasonable doubt may exist as to the nature of the affection under treatment. We may pause upon this point, and, postponing for the moment the consideration of the use of mercury in syphilis, first inquire what may be done without it—by what other means the disease may be treated—in what other way the primary local affection may be speedily cured—and by what other means the chance of secondary affections of the system may be lessened?

In the first place, there is every reason to believe that when a chancre is in its earliest stage, that is to say, while it is yet a vesicle or pustule, or the vesicle or pustule is but recently broken, and the ulcer is small and has little or no induration round it, the disease may be extirpated at once by destroying the surface of the ulcer with nitrate of silver. It is therefore prudent, when, after risk of infection, a vesicle or small broken surface is seen, thus to treat it. One practical use of M. Ricord's experiments is to confirm the propriety of this practice. If the artificial chancre is touched with nitrate of silver within three or four days from the commencement of the vesicle, the slough produced is always followed by immediate healing. If the application of the caustic is delayed two or three

days longer, it proves ineffectual; and when the eschar separates, there is but a larger ulcer of the character of that which preceded it. I have observed the same effects in ulcers of infection at the corresponding stages; and I perfectly believe that a chancre, taken at the earliest period, and thus destroyed, will not infect the system.

In the second place, if the sore, upon the separation of the eschar, presents again the character of chancre, or if the sore, when first seen by a surgeon, has already made some progress, no accidental inflammation being present, the treatment by lunar caustic may still be adopted or be persevered in. Such is M. Ricord's general practice: he continues to apply the nitrate of silver till the ulcer granulates, dressing the sore with lint, wet with a stimulating tincture; to which, if it produce pain, opium is added. Supposing, however, local inflammation to be present, this treatment would be inadmissible. Lint wetted with a saturnine and opiate lotion, or with the black wash, or water, or a bread poultice, would then be proper local applications. As general means, the body should be kept cool by low diet and occasional aperients, and the patient should abstain from exercise. If plethoric, he had better lose blood. The latter rules, however, are given as belonging to the non-mercurial treatment, when used indiscriminately. When that is resorted to, upon reference to individual peculiarity of constitution, these rules may likewise have to be modified for the same reason.

In the limited number of cases in which alone I am now arguing for the non-mercurial treatment, it is a question of little importance whether the ulcer heal something slower or as fast as if mercury had been employed. This question, abstractedly, is one upon which considerable difference of opinion prevails among the experienced army surgeons, to whose observations the profession is so much indebted for evidence we could have obtained from no other source. Dr. Thompson observes, that "under an antiphlogistic regimen, rest in the horizontal posture, and mild local applications, chancre and bubo have in every instance disappeared as speedily as he had ever seen them disappear in similar cases, where mercury had been employed." He mentions, in continua-

tion, that Mr. Hicks had found the same result of the non-mercurial treatment in the men affected with syphilis of the 95th regiment, of whom he had the charge. On the contrary side, Mr. Guthrie gives, as the result of his own observations, jointly with those of Mr. Dease, Dr. Arthur, and Dr. Gordon, what I am induced to think more likely to be the general result of non-mercurial treatment on primary sores. "With us," Mr. Guthrie observes, "where the ulcer had the characteristic appearances of chancre, dry lint alone was generally applied to it; where these signs were less prominent, a variety of applications were used; but there were a great number of sores, both raised and excavated, on which no application made the least favourable impression for many weeks. They did, however, yield at last to simple means, after remaining for a considerable time nearly in the same state, several of them having become sores of a large size previous to or in the first days after their admission. If they were ulcers without very marked appearance, and did not amend in the first fortnight or three weeks, they generally remained for five or seven weeks longer; and the only difference in this respect, between them and the raised ulcer of the prepuce, was, that this often remained for a longer period, and that ulcers presenting the true characters of chancre, required, in general, a still longer period for their cure—that is, from six, eight, to ten, twenty, and even in one case twenty-six weeks, healing up and ulcerating again on a hardened base."

The concurrent testimony of Mr. Rose's cases, and of Mr. Bacot, go to the same conclusion. It is strongly confirmatory of its correctness, that M. Ricord, an habitual non-mercurialist, speaks of the same form of chancre which Mr. Guthrie found thus tedious without mercury—the indurated, namely—as proving, in his own practice, equally refractory, unless he deviates from his usual method, and resorts to the specific. "Whatever may be the cause," he observes, "if it be certain that a well-directed local treatment leads very often to a complete cure of indurated chancres, *yet the cure so obtained is most commonly slow, and is liable to be imperfect.* The difficulty of thoroughly healing the indurated

chanere by ordinary means, and the good effect of mercurials in its treatment, have been the principal reasons," M. Ricord continues, "which have caused this variety to be considered as the exclusive type of primary syphilis, and mercury to be its sole specific."

The importance of the occasional use of mercury in the treatment of the primary symptoms of syphilis is thus forced upon us, when we set aside the consideration of its agency in preventing the entrance of the disease into the system. We have now to give attention to the latter question, the solution of which is again to be sought in the mass of evidence collected by the diligence of the army surgeons. Not, however, to run into too great length, I shall confine myself to quoting the results of the analysis given in Mr. Bacot's Treatise on Syphilis, of the entire evidence collected. Mr. Bacot represents the conclusions to be drawn from these sources to be the following:—

"1st. That all sores of the genitals, without exception, are curable without mercury. 2dly. That *secondary symptoms occur in the proportion of at least one in ten in those cases where no mercury is used, whilst, on the contrary, the proportion of such cases is only as one to seventy-five where that remedy has been employed.* 3dly. The possibility of curing nearly all the forms of the secondary syphilitic symptoms without the assistance of a particle of mercury. 4thly. The mildness of these symptoms, which, excepting in about half a dozen instances, were confined to eruptions on the skin, and ulcers of the throat. 5thly. That the period required for the cure of the primary sores by the non-mercurial treatment was not, in general, greater than where mercury was employed; though it is admitted that the cicatrices of the sores remain frequently in a state of disease after ulcerating again, and that the secondary symptoms, when not violent, are very tedious; and when apparently cured, would not unfrequently recur again and again."

If this analysis of the evidence collected is tolerably correct, it leaves no doubt as to the general preferableness of the mercurial to the non-mercurial treatment, upon the ground of greater security. Yet there is one feature in the preceding summary which is in fa-

vour of the latter, and which is quite of importance enough to deserve examination; I allude to the alleged mildness of the secondary disease, where mercury is not given. Upon this point it appears to me that there is probably a fallacy. There are no sufficient reasons for believing that the judicious use of mercury tends to aggravate syphilis. The alleged mildness of the secondary symptoms, when mercury has not been given, has most likely arisen from the cases with which they are contrasted having been cases where mercury has been administered more by routine than with discrimination, and therefore often in excess. It is in the same manner that I am persuaded that Dr. Fricke, of Hamburg, one of the ablest advocates of the non-mercurial treatment, has suffered himself to be deceived. We read in Professor Graves's instructive lectures, as a point of unfavourable contrast to the mercurial treatment, that the venereal wards, under Dr. Fricke's non-mercurial treatment, are now fresh and properly ventilated, and that the patients leave them with healthy looks; whereas formerly the foul smell of the wards could not be removed, nor the rooms nor beds kept clean, and "the air was tainted with the offensive odour of salivation and syphilitic caries." One does not wonder that, of the two alternatives, Dr. Fricke should prefer the former; but there is a mean between the two which may be preferable to either, namely, the employment of mercury, with the avoidance of the evils that often but not necessarily have gone with it.

Every observant hospital surgeon in London must have seen enough in his own practice to convince him of the efficacy of mercury in lessening the frequency of secondary lues. In the considerable number of patients who apply at the Middlesex Hospital with secondary symptoms, I find on questioning them that by far the majority have taken such courses of mercury as are considered by no one capable of extinguishing the disease. Occasionally, too, one has the opportunity of seeing protracted cases of primary disease, where the patient has been late in applying for relief, and where the secondary symptoms break out early, and with a rapidity and virulence, which, one is confident from the experience of

other cases, would not have happened had a mercurial course been commenced in proper time.

Thus, finally, are we led to consider mercury of an importance in the cure of syphilis, which rationally accounts for the strength and duration of the belief that it was a specific for the disease. What strikes one, in looking back to the history both of the disease and the remedy, from the time of Hunter to the present, is the following progress of men's opinions about them. The recognition, first, of the most decided characters of syphilis, and the adhesion to the belief that mercury is its specific remedy. Secondly, the observation of many cases which got well without mercury, or the course of which was very unequally influenced or even aggravated by mercury, and the impression that these were not true syphilitic disease. Thirdly, the multiplication of similar cases, as practitioners became bolder in relinquishing the use of mercury, and the establishment of some and the supposed establishment of other particular forms of venereal disease, to the treatment of which mercury was not applicable. Fourthly, the rejection of mercury altogether in all cases of venereal disease, and the proof that every case might be cured without it. Fifthly, the determination that mercury is nevertheless of use both in healing primary sores and in preventing constitutional lues; coupled with an uncertainty as to the exact cases where mercury is indispensable, and a constant doubt as to the quantity in which it should be used. This is our state at the present moment; and the error into which we are most likely to fall is, not the total abandonment of mercury, for no surgeon but will soon be driven from this practice by the fierce and early accession of secondary symptoms, which he will sometimes witness from its omission, but its indiscriminate use, and that, again, in excess.

The practical rules for the management of a mercurial course are few and simple. It should be commenced as soon as the character of the disease is determined. It is probable that the delay even of a few days materially lessens its efficacy towards preventing constitutional lues. For the same reason mercury should be given at once in a quantity, and in a manner, calculated

to affect the system as speedily as is consistent with keeping clear of its injurious agencies.

Now if a surgeon wishes to affect the system promptly with mercury in any other complaint, the usual prescription is two to three grains of calomel, with half a grain of opium, every eight or six hours. This is, therefore, in general, the best method in the present instance.

The administration of mercury in this quantity is to be carefully watched, and the dose is to be lessened as soon as its effects distinctly manifest themselves. These, where mercury agrees (which cases alone are at present under consideration), are an unpleasant coppery taste in the mouth, and a swollen and tender condition of the gums. In the most favourable cases no further sensible effects should be produced by the mercurial course. The condition of the fauces which has been described, and which is the measure of the due extent of mercurial action, should be maintained as nearly as possible at the same point. For the rest of the course, the quantity of from five to ten grains of blue pill daily, is commonly fully sufficient to secure the end proposed.

The duration of a mercurial course should be from five to six weeks. This is in part determined by the alterations of the sore. If the sore early loses its specific character, and begins to shew a disposition to healthy granulation, and the hardness has at the same time disappeared, then the shorter period specified may be enough. Here, however, we but feel our way blindly, and want more light and certainty. The knowledge which we want can only be obtained through the means of observation possessed by army surgeons; they alone have the opportunity of keeping under observation a sufficient number for a sufficient length of time to ascertain the eventual success of any plan of treatment. It is to be hoped that, in the same spirit of exact observation which has been already displayed, we may before long have determined for us by positive experiment, the shortest period and smallest quantity of constitutional effect necessary to give a mercurial course full efficiency.

In conjunction with mercurial treatment, the local treatment should be the simplest. Lint wetted with water, or

with a saturnine and opiate lotion, or the black wash, should alone be employed. But sometimes, when the hardness of the sore is gone, and its surface remains stationary, it is of use to touch it with nitrate of silver, to destroy the indolent edge, and stimulate action.

The diet should be plain; acids, and fruit, and green vegetables, and beer, being shunned. The patient's apartment should be well ventilated, and at a moderate temperature. Mercury renders a person more susceptible of cold; but, on the other hand, heat increases its naturally lowering tendency: so wine often becomes a useful medicine towards the close of a mercurial course. At the commencement of a mercurial course the patient had better not leave his room; exercise endangers the supervention of inflammation, and of the accidents of syphilis presently to be noticed. The bowels, again, should not be in a costive state either just before commencing mercury, or during the course. This is to be prevented by aperient medicine. Afterwards, going out daily is objectionable on these grounds alone:—the risk of irritating the part, or of incurring some of the consequences which exposure to cold, and still more readily exposure to cold and damp, produce. These risks being guarded against, the patient need not confine himself within doors. But it is to be observed that mercury does not act so quickly or so powerfully, when the patient is daily and freely exposed to the air, as when he stays in the house.

We may now proceed to the consideration of the various circumstances through which a mercurial course may be rendered either inefficient and nugatory, or in addition dangerous—the accidents of a mercurial course.

It may be well to premise, that some are so sensitive to mercury, that the first dose of the remedy will bring on more or less of several of the effects that are presently to be described; that their invasion, where every thing seems going on well, is often sudden and violent; and that the administration of mercury cannot, therefore, be watched with too much caution.

There are others whose constitutions seem hardly to admit of being affected by mercury. In these cases, confinement to a warm apartment, the use of the warm bath, and bleeding even, when not contraindicated by other circumstances, may be

employed with advantage. The preparation, again, of mercury may be changed, the Plummer's pill, or corrosive sublimate, may be given in place of calomel alone or blue pill, or the remedy may be applied externally, and introduced through the skin.

Corrosive sublimate may be administered in the dose of an eighth to a sixth of a grain, made into a pill with bread, three times a day. It is best to give it with food, which protects the stomach from its direct agency. For mercurial frictions, a drachm of the strong mercurial ointment may be daily rubbed into the arms and thighs and legs. There are are some whose systems can only be affected by a combination of the two methods, and with whom mercury then produces its common and proper effects. But its use is not to be blindly pressed in every case of this sort, in the expectation of certainly attaining the desired end by perseverance: because, in the first place, any of the injurious effects presently to be noticed may suddenly supervene, the system becoming at last rapidly saturated; and, in the next place, it may be made evident by other than the usual signs that the mineral is acting upon the constitution. The patient may be paler, a little thinner, his pulse more frequent; he may be depressed and irritable; he may sweat profusely at night: the sore at the same time may improve. But whether the latter effect take place or not, the attempt to produce any further sensible impression upon the system in such a case should be abandoned, and the quantity of mercury administered should be much lessened.

The most frequent accident that disturbs a mercurial course is the supervention of diarrhœa, quickly running into dysentery. Such an attack begins with loose stools, followed by watery evacuations and griping, and leads to discharge of mucus and blood, with pain and tenesmus. Attacks of this nature are liable to be brought on by imprudence in diet, or exposure to cold, or arise from the dose of mercury not being guarded by a sufficient dose of opium. The diarrhœa may be checked by astringents combined with cordials and opium, and the dysentery by the same, joined with enemata of mucilage of starch and laudanum; but it is necessary, besides, to desist for two or three days from the further exhibition of

mercury. Some have bowels so irritable, that the dysentery returns as soon as mercury is resumed; in such cases recourse again must be had to the endermic method.

In some an eruption upon the skin is produced by mercury, which is called *hydrargyria*, or *eczema mercuriale*. It is shown by large red patches, which, on close inspection, are covered with minute vesicles, and are attended with heat, and itching, and irritation, not unlike that of nettle-rash. Sometimes considerable fever is present, and sore throat, and redness of the conjunctivæ. The eruption commonly appears on the belly and thighs, but it is liable to invade other parts in succession. The vesicles breaking, a slight and partial incrustation, with considerable soreness, follows. Cooling medicines in the first instance, with the omission of mercury; and, in the second, the application of simple ointments to the sore surfaces, or dusting them with hair powder, or *lapis calaminaris*, and bathing with a saturnine lotion, or a weak solution of sulphate of zinc, are appropriate remedies. Sometimes the eruption becomes in part pustular, and the fever runs higher, and assumes a dangerous typhoid character.

A most troublesome accident is the supervention of pyralism, with inflammatory swelling of the face and tongue, severe face-ache, and ulcers of the fauces, with aggravated fœtor of the breath; this distressing state of things may supervene very suddenly upon the administration of too much mercury. The means to get rid of the superfluous mercurial action consist in good ventilation of the patient's apartment, saline aperients, and an astringent gargle for the mouth. A weak solution of chloride of lime forms a useful wash to correct the fœtor, when it does not prove too irritating.

Sometimes the excess of mercurial action spends itself upon the throat alone, which inflames and ulcerates; the soft palate and tonsils appearing of a deep red colour, with small ulcers on the latter. Sometimes a deceptive appearance of ulceration is produced by aphthous-like patches on the tonsils, which are viscid secretion in the excretory orifices. If this disorder supervene towards the close of the mercurial course, it forms no sufficient reason for its interruption, but the quantity of mercury should be lessened.

Occasionally the irritation caused by mercury falls on the sore, which spreads, being with the parts around highly inflamed; this is mercurial phagedæna, which, if the course is not then suspended, and proper means of getting the mercury out of the system adopted, may go on to sloughing.

There are few in whom the nervous system is not more or less affected by a course of mercury. With a small number the effect is that of pleasant exhilaration and an unusual elasticity of spirits. With most, it consists in depression, and irritability of temper. With some, when mercury is given to excess, the imagination becomes excited, the thoughts hurried, and the mind, unable to stop or collect itself, is on the verge of temporary derangement. This I not long since witnessed in the case of a young gentleman, who, thinking that he was not affected speedily enough with mercury, had rubbed in nearly an ounce of ointment in the space of forty-eight hours.

But the most serious effects of mercury upon the system are those first described by Mr. Pearson, under the name of mercurial erethism. They consist in depression of the heart's action and of the nervous system, attended with irritability of the stomach. Mr. Pearson says, "Erethismus is characterized by great depression of strength, a sense of anxiety about the præcordia, frequent sighing, trembling, partial or universal; a small quick pulse, sometimes vomiting, a pale contracted countenance, a sense of cold." When the patient is in this state, any bodily exertion, whether sudden or otherwise, such as hastily rising from a chair or merely walking across the room, may cause immediate death: the patient faints, and does not recover from the syncope.

In one case which I witnessed, there was headache, faintness on exertion, a quick irregular pulse, paleness, nausea; in another, oppressive sense of faintness, particularly supervening at the instant of going to sleep, and attended with a feeling of suffocation. In a third, with less prostration, obstinate and protracted vomiting. In Dr. Bateman's case, described by himself, the symptoms were ushered in by violent and irregular action of the heart. The indications of treatment are, to give stimulants; of which, small doses of brandy and soda-water (laudanum being added if the

stomach or heart are very irritable) are the best—to expose the patient to the freshest air—to discontinue mercury—to prohibit all bodily exertion—to give light nutritious food, as soon as the stomach will digest it.

[To be continued.]

---

THE value of experiments made for the purpose of observing the growth of bones, and more remotely the general process of nutrition, by feeding growing animals on madder, has been, at different times, very differently estimated. They have been supposed by some to afford the only certain proof of a constant change of particles in nutrition, while by others they have been considered so vague and uncertain as to admit of no profitable application; and it would be easy to quote from the highest physiological authorities expressions of such doubt, with respect to the conclusions to be drawn from them, as would at once justify any attempt to explain their difficulties and apparent contradictions.

Herissant, who first distinctly explained the combination of animal and earthy matter in the bones, knew that it was only with the latter that the colouring matter of madder united; but it was Dr. Rutherford\* who first, in his lectures, described the union as an evident example of chemical affinity operating in the living body, and showed its identity with the process, well-known to dyers, in which a soluble colouring matter unites with some insoluble substance, called a *mordant*, and thus becomes itself fixed in what is termed a *lake*. He therefore simply explained the reddening of the bones as the result of the union of the colour-

ing matter of the madder absorbed into the blood with their phosphate of lime.

It was known that if the madder were given for some time to a young animal, its bones would be partially reddened, and that if the use of madder were then discontinued for some time, they would again become white. In accordance with the commonly received explanation of nutrition by a constant removal of old, and deposition of new particles, it was therefore supposed, that in the first change the redness arose from the deposition of reddened phosphate in the place of the colourless phosphate that existed previously; and that, in the second, the coloured phosphate was absorbed, and uncoloured phosphate deposited in its place. But Mr. Gibson\*, in a paper which had for its object to prove the insufficiency of the madder experiments in their supposed application to the subject of nutrition, endeavoured to show that the return to whiteness of the bones, when madder is discontinued, might be explained otherwise than by supposing red particles of phosphate of lime to be removed, and white ones deposited in their places. He thought that if there were any substance in the blood which had a greater affinity for the colouring matter than phosphate of lime, it might abstract the colour from the bones, though the earthy matter remained longer fixed in them. He advanced the opinion, founded on an experiment, that the serum of the blood has such a greater affinity; and he therefore explained the processes of reddening and whitening, by supposing that the phosphate of lime of the bones does not become coloured till the serum has been saturated; and that after being coloured, it again becomes white, when the serum, having lost its condition of saturation, by the various secretions in which the colouring matter is separated from it, again exercises its superior affinity. It is, I believe, from Mr. Gibson's paper that much of the present uncertainty has arisen, and a correction of some of its errors will go far to establish the real value of experiments of this nature, at least in their applications to the growth of bones.

The chemical properties of madder,

---

\* R. Blake on the *Teeth*, Dublin, 1801.

\* *Memoirs of the Literary and Philosophical Society of Manchester*, Vol. 8, (Ser. 2, v. 1.) p. 146.

on which its application in this physiological question depends, are briefly these: the fresh root\* imparts to cold water a yellow hue; to hot water, a more or less deep red hue. If to the latter solution there be added, first, phosphate of soda, and then hydrochlorate of lime, the phosphate of lime, which is precipitated, carries down with it the red colouring matter, and leaves the solution of a deep-yellow colour.

The same red colouring matter has also a considerable affinity for all albuminous fluids, and, therefore, for the serum of the blood. The explanation of the phenomena produced in living animals fed on madder, depends simply on the decision whether its affinity for serum be greater than its affinity for phosphate of lime; in other words, whether serum can or cannot remove the red colouring matter from its union with the earthy matter of the bones.

The experiment from which Mr. Gibson concluded that serum has a greater affinity for the colouring matter of madder than phosphate of lime has, is thus detailed by him:—"I took one dram of the phosphate of lime, tinged, as in Dr. Rutherford's experiments, and exposed it for half an hour to the action of two ounces of fresh serum, at the temperature of 98°. By this operation, the serum gradually acquired a red tinge, whilst the phosphate of lime was proportionally deprived of colour. In a comparative experiment, a similar quantity of phosphate of lime was exposed to the action of distilled water, under similar circumstances, but no change took place."

On repeating this experiment, I found that when the coloured precipitate of phosphate of lime and madder was washed with distilled water, no tinge of red was imparted to the water, but it acquired a bright-yellow hue. If, on the other hand, a similarly coloured precipitate were washed with serum, that fluid acquired (as Mr. Gibson says) a more or less deep crimson tint. But by filtering a large quantity of serum through the precipitate, I found that only the first portions that passed through were deeply reddened, that the succeeding portions became gradually paler, and that after a certain time no colour whatever was

imparted to the serum, although the precipitate retained as deep a colour as is ever seen in the reddened bones. In like manner, by filtering repeated quantities of distilled water through a similar precipitate, it ceased at last to acquire any yellow colour. From frequent repetitions of these experiments, with the same results, I was led to believe that when the phosphate of lime is precipitated in a solution of madder, it carries down a certain quantity of colouring matter more than that which chemically unites with it; and in this view the explanation of the apparent difficulty is at once clear. When the reddened phosphate of lime is washed with cold or tepid water, only the uncombined yellow colouring matter is dissolved; but the serum having an affinity for the red colouring matter, dissolves all that is not chemically combined with the phosphate of lime, and then also ceases to acquire colour.

In order, therefore, to prevent serum from being coloured, by contact with the precipitate of madder and phosphate of lime, it is sufficient to employ any means that will prevent or remove the admixture of free madder with the precipitate. This may be effected by repeatedly boiling the impure precipitate, or by long continued washing with hot water; but it may be done more conveniently by filtering serum through it till it ceases to acquire a red colour; after which, any further quantity may be passed through, without changing either its own colour or that of the now pure and still deeply coloured phosphate. I have washed a few grains of precipitate, thus purified, with 12 ounces or more of fresh serum, without producing the slightest apparent change in either.

These facts are sufficient to prove that serum has no power to separate the colouring matter of madder from its chemical combination with phosphate of lime; but, on the contrary, phosphate of lime will remove the same colouring matter from its combination with serum. Thus, if to a solution of madder, in serum, there be added, first, phosphate of soda, and then hydrochlorate of lime, the whole of the colouring matter is precipitated, though more slowly than from an aqueous solution, and the serum presents again its natural yellow hue.

As phosphate of lime, therefore, has a more powerful affinity for the red

\* It is essential to the success of all these experiments that both the madder and the serum should be used in as fresh a state as possible.

colouring matter of madder than serum has, the serum need not be saturated before the bones can acquire colour. Nor, indeed, does the serum ever become saturated in the living body; if it did, so intense would be its colour that it would be impossible to distinguish it from that of the venous blood itself. But in two cases in which I examined the blood of rabbits, which had been fed for several months with madder, the serum had its natural colour, and Dr. Rutherford\* says, "that large quantities of madder are necessary to communicate any sensible colour to it."

It is evident, then, that madder, directly it is absorbed, will unite with whatever phosphate of lime is present in the blood; but I am, for many reasons, inclined to believe that the chief, if not the whole union, takes place at the growing bones in the very act of nutrition. Thus, every particle of phosphate of lime that is deposited, during the taking of madder, is reddened, and as such particles accumulate amongst and around the white particles already existing, the bone acquires a more or less intensely red colour. But the coloured phosphate of lime regains, after a time, its white colour; though not, as Mr. Gibson supposed, by the serum exercising a superior affinity, as soon as it loses its condition of saturation, for the serum neither becomes saturated, nor has it, when below saturation, any power to bleach the coloured bone. The bleaching is probably effected by a gradual decomposition of the madder, as reddened skeletons gradually lose their colour when exposed to air and light: in both cases it is a very slow process†, and in the living animal a long period of abstinence from the use of madder must pass before any change of colour is effected; so that this gradual bleaching, though it may be important in explaining general nutrition, need not be taken into consideration in any of the experi-

ments that have yet been made to determine the mode of growth of bones.

One of the most important facts to be borne in mind, on this subject, is that the madder colours only those particles of phosphate of lime which are deposited during its use. Du Hamel knew this, as well as his knowledge of the chemical composition of the bones permitted him, but the fact has been very generally disregarded, and every writer on the subject, since the time of Haller, has implied that the madder, when taken into the blood, can impart its colour to the phosphate of lime already existing in, and forming part of the bones\*. Direct experiment proves the contrary; the bones of old animals receive the red colour from madder very slowly, and never, under any circumstances, acquire more than a slight tinge of it. I gave madder to an old rabbit for twelve months, and at the end of that time its bones had acquired so slight a tinge of redness that it was doubtful, to many, whether they had been altered at all. In another rabbit, 12 months old, and fed for 4 months, the redness was decided, but extremely pale. All the experimenters on this subject affirm, in general terms, that the bones of old animals are coloured more slowly and less deeply than those of young ones;† but none of them detail their observations. In most of the cases where old animals were fed on madder, to observe the reparation of fractures, the colour of the bones is not mentioned at all‡, but on one occasion Detlef§ says, "that the bones of an adult pigeon, after several days use of madder, were quite white, while the callus, formed around some fractures, was bright red." The general result of Du Hamel's numberless experiments are conclusive on this point; he says||, "that the bones of old animals did not acquire colour till after a considerable time, and that even then the colour was always pale." It is evident, from these facts, that the phosphate of lime, already deposited before madder is

\* L. c. p. 141.

† Du Hamel is quoted by Haller, Gibson, John Bell, and many others, as if he had stated that the bleaching of reddened bones is a rapid process. In the only place to which their quotations can refer (*Mémoires de l'Acad. des Sc.* 1739, p. 4), he merely says, that "the redness of one of the bones, in the wing of a pullet, as seen through its transparent skin, gradually vanished;" but in Fougereux (*Mem. sur les Os.* p. ix.) it is expressly stated that Du Hamel considered himself to have been deceived in this observation, and his subsequent experiments showed that the apparent fading, in this and many other cases, was the result of the deposition of white layers of bone externally to, and obscuring the red.

\* I have no doubt that John Hunter was acquainted with the truth, although, as Mr. Owen observes, "there is a contradiction between the observations in different parts of his writings." See Hunter's Works, by Palmer, Vol. 4, p. 315, and Vol. 2, p. 17.

† See Haller, *Elementa Physiologiæ*, Vol. 8, p. 333.

‡ As in Detlef's experiments, xii. and xiii., in Haller's *Opera minora*, V. 2, p. 471.

§ L. c. p. 466.

|| Fougereux, l. c. p. vii.

taken, is not coloured by it; else the old bones should acquire the red colour as soon and as fully as the young ones, which, on the contrary, become as much tinged, in 24 hours\*, as the bones of adults are in 12 months.

To explain the pale redness which old bones may at last acquire, it is not necessary to suppose that old white particles are removed, and new red ones deposited in their places; for long after the bones of an animal have ceased to increase in size, that is, long after the animal has attained its full stature, there is a constant increase of their density, by the interstitial deposition of additional earthy matter, whether alone, or as Dr. Rees' analyses† render more probable, in combination with animal matter. Now, every particle of phosphate of lime thus added to the bones of a full grown animal, feeding on madder, would have a red colour, and thus by the gradually increasing number of red particles interspersed among the white ones, the bones acquire, at last, a distinct, though pale red hue, but never attain the same intensity of colour as those of growing animals, in parts of which so much more phosphate of lime is being deposited.

The same conclusion, that only those particles of phosphate of lime which are added to the bones during the use of madder, are coloured, may be drawn from the experiments in which, by the alternate use and disuse of madder, alternate rings of white and red bone were obtained; from the deep redness which the ossified callus around fractures acquires, while the bones themselves, even in young animals, become only pale red; and from the light colour which is imparted to those bones in young animals, which attain nearly their complete hardness at an early period, as the *ossicula auditus*‡.

The result of all these facts is briefly this: when a growing animal is fed on madder its red colouring matter is absorbed, dissolved in the serum, and carried with the blood to all parts of the system: at the bones it is immediately precipitated with every particle of phosphate of lime that is being formed and deposited in them, but it has no influence on the phosphate of lime already exist-

ing in them before its administration, nor has the serum any chemical power to remove the colour from the phosphate of lime once tinged.

After these general observations, the experiments of Du Hamel and others may be more profitably considered. In reference to the increase of diameter of the shafts of long bones with medullary canals (to which the experiments almost exclusively relate), Du Hamel\* shewed that it is effected by the deposition of osseous matter on the external surface of the walls, by experiments in which he alternately gave madder with the food of growing pigs, and withheld it from them†. From among a great number of such experiments, he relates the following‡:—A pig, six weeks old, took madder for a month; then ceased from it for six weeks, and was then killed. In the femur and tibia the medulla was surrounded by a moderately thick layer of white bone; this was encircled by as thick a zone of red bone, which, again, was covered by a moderately thick layer of white bone. A second pig, aged two months, took madder for a month, then ceased from it; then took it again for a month, and was then killed. In this case there were, around the medulla, first a white layer, then a red one; then a second white, and lastly a second red zone. A third pig was treated like the second, but, after the second period of taking madder, returned, for some time before his death, to common food; and in his cylindrical bones there was, in addition to the four layers found in the second, a fifth layer external to them all, and of a white colour.

It is not necessary to adopt Du Hamel's first opinion, that these alternate layers were formed by the successive ossification of layers of the periosteum. It is evident, indeed, that in all those of his papers which are commonly quoted, he understood by periosteum something very different from the thin fibrous membrane to which that name is generally applied; and it is satisfac-

\* *Mémoires de l'Acad. des Sciences*, 1739-41-42-43.

† Mr. Gibson, who appears to quote from John Bell's *Anatomy*, speaks of these experiments as performed on cocks, and then, joining with Mr. Bell in his ridicule of them, leaves the reader in doubt whether Du Hamel reported falsehoods or absurdities. There is not any mention in any of Du Hamel's papers of experiments of this kind performed on birds.

tory to find that he himself, at a later period, entirely gave up the theory for which he has ever since been ridiculed. In a letter to M. Bonnet\* (which all his commentators have overlooked), he admits that he was led, by the writings of Malpighi, into the error of supposing that the new wood of growing trees is formed from the bark; and from this had drawn the incorrect analogy of the formation of the new bone from the periosteum. When, however, he had more minutely studied the growth of trees, he found (according to the opinion at present received) that in exogenous plants the new wood is formed from a layer of soft substance, the cambium, deposited between the alburnum and the bark, which, hardening and dividing, contributes to form on the one side new wood, and on the other new bark. Then, returning to the examination of bones, but still with the idea of the analogy of their formation to that of wood, he says (p. 165), "The wood increases in size, by the addition of thin layers which form between the wood and the bark. The bones increase in size, by the addition of thin layers which form between the periosteum and the bone."

Neglecting, however, the unnecessary and loose analogy between bones and trees, in which even Du Hamel's faith was at last very weak, it is impossible not to deduce, from the experiments described, that the growth of long bones in circumference is effected by the successive addition of external layers, whether (as is by far most probable), they be produced from the bone already formed, or (as Du Hamel imagined) from the periosteum. Admitting, for a moment, Mr. Gibson's supposition of the superior affinity of serum for the colouring matter, it is impossible that the white layer supposed to be deposited during the disuse of madder, should be a part of the old reddened bone, from which the madder has been removed after having been redissolved in the serum; for this would not account for the alternation of colours in the several layers. In the case of the third pig, for example, if one supposes that, while madder was being taken, the part of the bone formed before and

during that time was reddened, but that when the madder was discontinued the serum was occupied in removing the colour, it is yet inexplicable why it should remove it in layers, so that at the animal's death, instead of a diffused pale redness or total whiteness, there should be three zones of white bone and two of red. If too, it were possible that in the first experiment the outer part of the red zone had been decolourized after the madder was discontinued, it cannot be supposed that the same change was effected in the third; because in it, had such been the case, the layer of reddened bone nearest to the medulla, which had been exposed to the action of the serum during two periods of disuse of madder, ought certainly to have been completely blanched. Thus, were Mr. Gibson's opinions true, they would involve an inexplicable contradiction.

Du Hamel's experiments are confirmed by all that have been related since by Hunter, John Bell, and others\*; and the view deduced from them, of the constant super-addition of layers during growth, is supported by other experiments of a different kind. Thus Du Hamel† passed a wire round the bone and periosteum of a young pigeon, and tightened it: after twenty days the bone broke beneath the wire, and on examination, it was found that there was no increase of size in the shaft, in the line under the wire, but that a thick border of bone was formed on each side of it. In another case‡, a ring was put round the tibia of a young pigeon, under the periosteum; the growing wall was cut through by it, and, when the parts were examined, the ring was found not larger than the medullary canal. An experiment confirmatory of these was made by Mr. Hunter§; in which shots, placed in holes in the wall of a fowl's bone, passed into the medullary canal. Mr. Stanley's experiments|| are similarly confirmatory of Du Hamel's; and he remarks from them, that a piece of

\* But none of the later observers appear to have avoided any of the many sources of fallacy which Du Hamel pointed out; and hence, probably, in some measure, the uncertainty into which they have fallen. (See especially Du Hamel's *Quatrième Mémoire*, in the vol. for 1743.)

† *Mémoires*, 1742.

‡ *Mémoires*, 1743, p. 102.

metal fixed in the wall of a bone, soon becomes imbedded in it by the growth of new bone over it\*.

It is evident, then, from all these experiments, that the growth of a long bone, in its whole circumference, is effected by the successive addition of new layers to its external surface; the coincident increase of the size of the medullary canal is effected by the removal of layers from its internal surface. Du Hamel was aware of the necessity of two such simultaneous and opposite processes; but while he correctly illustrated the external addition, he ascribed the other to an action which he vaguely called expansion. Mr. Hunter more strictly explained it by a reference to the action of the absorbents. The whole truth at present known is included in a union of the correct opinions of each of these authors. The process of external addition is continued for a longer time than that of internal removal; and later than either, as well as coincidently with both, there is also a constant, but far less abundant, interstitial deposition, tending to the increase of the bone's density without any increase of its size.

In respect to the increase of bones in length, the use of madder is less distinct, though it fully confirms the results of other experiments, whose evidence is more palpable. Of the latter, the following are found in Du Hamel's papers†:—

I. Two moderate-sized holes were made in the middle of the shaft of a little lamb's fore-leg, and after sixteen days the space between them had increased from 1 inch to 1 inch 2 lines.

II. In the tibia of a dog, aged 15 days, five holes were bored: No. 1 near the proximal end; 2, nearer the middle; 3, exactly in the middle; 4, nearer to the distal end; and 5, still nearer. Fifteen days after, the middle hole (3) was a line further from each of those nearest to it (2 and 4), and 4 was five lines further than at first from 5.

III. Four holes were made in the tarso-metatarsal bone of a young pigeon: 1, near the foot; 2 and 3, on each side of the middle; 4, near the proximal end. Eight days after, 2 and 3 had not changed their distance, but

1 was one-fourth of a line further from 2, and 4 was half a line further from 3.

IV. In a chicken, six weeks old, with a tibia (?) two inches long, a piece of wire was stuck in, half an inch from the distal end of that bone; a 2d piece, half an inch from the first; a 3d, half an inch from 2; and a 4th, half an inch from 3, and half an inch from the proximal end. After seven weeks, the bone was three inches long: 1 was now nine lines from its distal end; 2 was half an inch from 1, and half an inch from 3; 3 was fifteen lines from the proximal end; so that this bone had grown nine lines at the proximal end and three lines at the distal, but had not increased at all in the middle.

Hunter's experiments confirm those of Du Hamel; as well those mentioned by Sir Everard Home\*, in which the experiments (like some of Du Hamel's) must have been made on rather old pigs, as that of which the preparation remains in the museum of the College. In these experiments no general mention is made of a greater increase at one end of the bone than at the other. In Du Hamel's the chief increase was at the proximal end; but in a series of experiments in which I assisted Mr. Stanley, there appeared to be certain differences in this respect in different animals. Thus, in two experiments on the tarso-metatarsal bones of pigeons, the increase was, as in Du Hamel's on pigeons and chickens, chiefly at the proximal end; while in the ulna of a kitten it was chiefly, and in the ulnae and radii of dogs entirely, at the distal end. In other respects these experiments† entirely confirmed those of Du Hamel. None of the animals used were very young, and in none was there any increase of length in the middle of the shaft.

The general result of these experiments, then, is that which Du Hamel stated—that the increase in the length of bones is effected by the growth of those parts which are not yet hardened. Ossification commencing in the middle of the shaft, and proceeding rapidly towards its extremities, it is only in very young animals that any increase in the middle can be perceived; the later increase of length is due to the addition of osseous matter to the parts not yet hardened;

\* There are preparations illustrating this fact in the Museum of St. Bartholomew's Hospital.

† Memoires, 1743, p. 111.

\* Hunter's Works, by Palmer, vol. iv. p. 317.

† The preparations illustrative of them are in the Museum of St. Bartholomew's Hospital.

and at the latest periods of growth is effected entirely by the ossification and reproduction of the intermediate cartilage between the shaft and the epiphysis.

In their applications to the explanation of the growth of bones, experiments with madder are thus proved to be conclusive: with a knowledge of the principles on which they depend, and with a careful avoidance of some sources of fallacy that have been pointed out, they may be employed with entire confidence; they afford to the observer the means, as it were, of branding with his own mark every particle of phosphate of lime that is deposited during a given time.

Their applications to the general doctrine of nutrition are less certain: for, in the first place, it is not clear that the laws which govern the production and maintenance of the earthy and inorganic matter of bones are applicable to the nutrition of soft parts; and if they be, the result of the madder experiments is at present in this point of view entirely negative, if not opposed to the idea of a constant mutation of particles. Seeing that the blood containing madder has no evident influence on the phosphate of lime already deposited in the bones, and that, on the other hand, blood not containing madder does not possess any chemical power to abstract the colour from the coloured phosphate of lime, it would appear as if there were no influence exerted during the state of health between the contents of the capillary system and the earthy matter already existing in the bones. And as, moreover, the bones of old animals are coloured by madder only to that degree which appears explicable by their increase of density, it would seem as if, in the state of health, or in what I would call the state of *nutritive equilibrium*, the earthy matter of bones undergoes no change.

compared the blood-discs of some of the rarer animals in the Zoological Gardens, and give, in the present communication, the result obtained from the following species:—

Order PACHYDERMATA.—Elephant (*Elephas Indicus*), male, nearly full grown.

—Rhinoceros (*Rhinoceros Indicus*), male, full grown.

RUMINANTIA.—Dromedary (*Camelus Dromedarius*), male, full grown.

—Giraffe (*Camelopardalis Giraffa*), male, nearly full grown.

—EDENTATA.—Armadillo (*Dasypus 6-cinctus*), male, full grown.

The blood-discs were examined as they floated in the serum; also in a portion of blood thinly spread and rapidly dried upon slips of glass; lastly, as preserved in a solution of common salt of the strength of ordinary serum.

The observations were made by a Ross's Wollaston's doublet of a 1.8th inch focus, with Dujardin's illuminator, in the compound microscope belonging to the Royal College of Surgeons, and repeated, by the kind permission of Dr. Arthur Farre, with the same power and illuminator in the excellent microscope lately completed by Mr. Ross for that gentleman.

I have also to return my best thanks to Mr. Youatt, medical superintendent to the menagerie of the Zoological Society, for his prompt and obliging aid in obtaining the blood for my examination.

The blood from the *Elephant* was taken from a small vein on the side of the ear.

The red particles presented the usual figure characteristic of the mammiferous class, viz., the circular, flattened, slightly biconcave disc: their size varied more than usual, but that of the greatest number exceeded, by about one-fourth, the average-sized human blood-disc, which I take for the present comparison at 1-3500th of an English inch\*.

\* This is, perhaps, somewhat less than the true standard; but the difficulty of arriving at this is increased by the variation in the size of the average-sized blood-discs of different individuals, as well as by the difference which the blood-discs of the same individual present. I have been favoured by Mr. Bowerbank, whose great skill and accuracy in microscopic investigations are well known, with the following results of his examination of the blood-discs in four individuals, three male, and one female:—

The average-size of the blood-discs of the first

---

CONTRIBUTIONS  
TO THE  
COMPARATIVE ANATOMY  
OF THE  
BLOOD-DISCS, OR RED PARTICLES  
OF THE  
VERTEBRATE ANIMALS.

By RICHARD OWEN, Esq. F.R.S. &c.

[For the London Medical Gazette.]

In answer to an appeal from my friend Prof. Wagner, I have examined and

The largest blood-discs of the elephant were twice the size of the ordinary sized human blood-disc; the smallest equalled them in diameter: hence, the blood-discs of the elephant are of a larger size than those of any other mammiferous animal hitherto examined; but I need hardly observe that this relation of the size of the blood particles to the bulk of the individual is by no means constant in the *mammalia*, and that the discrepancy in this respect is still more remarkable in the lower classes.

The action of the salt solution upon the blood-discs produced a slight diminution of their size; and the number of those which presented the concave, or basin-shaped figure, was greater than in the recent blood. A few of the minute chyle (?) or lymph (?) particles were present, but I could not distinguish, in any of the portions of the elephant's blood examined, that variety of form in the blood discs which Prof. C. H. Schultze has described in the blood of an elephant, killed at Potsdam, by means of hydrocyanic acid, and which induces him to describe the blood of this mammiferous animal as containing in itself all the various forms of particles which characterize, respectively, the blood of insects, mollusks, fishes, reptiles, and mammals\*.

*Rhinoceros*.—The blood of this animal was obtained by a small incision in the upper lip, and was consequently of a mixed arterial and venous nature. The huge creature being attracted by a favourite dainty presented to him by his keeper, seemed quite insensible to the operation, and quietly allowed the blood to be collected as it trickled down.

The blood-discs presented the usual mammiferous form, and a less variety of size than in the elephant. The average diameter is one-sixth less than that of the human blood-disc. The largest sized blood-discs of the rhinoceros have a diameter of 1.3800th of an inch; the smallest, 1.5200th.

Among the accidental circumstances

was, in fractions of an English inch, 1.3687, the extremes being 1.4545 and 1.3279.

In the second individual, a female, the average size was 1.3474, the extremes being 1.3891 and 1.3105.

In the third individual, the average size was 1.3343, the extremes being 1.3922 and 1.2754.

In the fourth individual, the blood-discs presented the remarkably large average-size of 1.2861, the extremes being 1.4166 and 1.1862.

\* Muller's Archiv. fur Phys. 1839, p. 252.

observed in the examination of the blood of the rhinoceros, I may mention, that although that portion spread on glass was dried under the same circumstances as were the portions of blood obtained from other animals, a far greater number of the particles presented the granulated or mulberry character than was observed in the blood of the other quadrupeds. Some of the particles examined while floating in the serum, likewise presented the granulated contour.

*Dromedary*.—In inspecting the blood of this animal, which was obtained from a slight incision in the skin of the leg, I had the gratification of appreciating the accuracy of Dr. Mandl's recent interesting discovery of the elliptical form of its blood-discs. These present fewer differences of size than in the rhinoceros, but among the elliptical particles there were a few which presented the circular form. The long diameter of the average-sized elliptical discs was 1.3800th of an inch, the short diameter, 1.6500th.

*Giraffe*.—The blood of this animal, — mixed arterial and venous, — was obtained from an incision in the integument of the face, and presented the particles of the circular form, as in the ox, and ordinary ruminants, and in the mammiferous class generally. The average size of the particles was nearly one-third smaller than those of the human subject; the largest, which were few in number, measured 1.4000th; the smallest, 1.4800th of an inch: the average size, 1.4500th. The result of the examination of the blood of the largest of the ruminating tribe is interesting, inasmuch as it indicates that the size of the blood particles relates to the condition of the whole organization, rather than to the bulk of the species. It would appear, from the examination of the blood-discs in the goat, sheep, and ox, that an unusually small size of the blood-discs was associated with the peculiarities of the ruminant structure.

*Armadillo*.—The blood-discs of this little quadruped rather exceed in size those of the rhinoceros; but the varieties and size in different particles or vesicles have a more limited range. They present the usual mammiferous form. The average diameter is 1.3300th of an English inch.

CASE OF POISONING BY  
MURIATIC ACID.*To the Editor of the Medical Gazette.*

SIR,

THERE being, I believe, (in this country at least) no instance on record of poisoning by muriatic acid, and only one on the continent, as mentioned by Orfila, I have taken the liberty of sending you an account of a case of this nature which was brought to this hospital on the 17th of last month, and which I trust will be found worthy of a place in your widely circulated periodical.

The subject of the present communication was Frederick York, a man of industrious habits, about 40 years of age, and by trade a wadding-maker. On the morning of the 17th, the day in question, he came to his employment at his usual time, and nothing singular was remarked in his manner, with the exception of his being rather more merry than ordinary. About 10 o'clock he asked his master to allow him to leave his work for an hour or two, as he wished to go to the London Hospital (of which institution he was an out-patient); his master having consented, York immediately left for the purpose, as it was supposed, of going to the hospital; but instead of doing so, it was ascertained afterwards, that he prevailed on a boy, who worked at the same establishment as himself, to accompany him to a chemist's in the neighbourhood, of whom he wished to purchase some muriatic acid to put into some size he was going to use. On their way to the chemist's York called at the house of a female friend, of whom he borrowed two-pence and a small phial; in his conversation with her he complained of having been ill-treated, and as far as she is able to recollect, he stated "that either he or somebody else should suffer for it," or words to that effect. On arriving at the chemist's, York requested the boy to remain outside the shop, whilst he went in to purchase the acid; on receiving it he placed it in his bosom, between his shirt and waistcoat, and by some means or other, most probably from the unsoundness of the cork, some of the contents of the phial were spilt about his dress, especially about his waistcoat, which was noticed by his master and others to be of a red colour where the acid had come

in contact with it—a fact that will be mentioned again presently.

When he got back to his employment again he took the phial from his bosom and desired his master to smell it, which he did, and on returning the phial to York, he added that he must be careful of it, to which York replied that he would, for he was well aware that it was strong poison. Some little time after this, the boy who accompanied him noticed that he put into the size a small quantity of the acid, not more than a table-spoonful. About half past two o'clock he complained to those who worked with him of being unwell, and expressed a wish to go home to lie down, which they advised him to do; he therefore left his work, and on arriving at his house (which was about three-quarters of a mile from the factory at which he worked) he was seen by a female lodger, to whom he told that he had taken poison, and complained greatly of the pain in his throat and stomach; she did not believe him at first, but advised him to go and lie down on the bed which was in an adjoining room; in proceeding to do so he fell, and in falling, struck his head against the door post; she now became alarmed, and informed some of her neighbours of what had happened, and by their assistance he was lifted up and placed in a chair, when he leant back and said, "I am a dead man." After this he recovered a little, and took a cup from a shelf and went to the water jar, and having filled it drank the contents, and seemed for a little time much easier; but shortly becoming worse, his friends procured a coach for him, and he was brought off to this hospital, where he was quickly seen by the apothecary, who administered to him magnesia, milk, and the other remedies employed in such cases, all of which failed to relieve him; he complained more and more of the pain in his throat and stomach, and repeatedly asked for water to drink. From the hour of his arrival, which was about five o'clock in the evening, he lingered on till five on the following morning, when he expired, being about twelve hours after his admission. Shortly before his death he told his wife that he had taken muriatic acid; and this his friends state was the name that he gave to it, to all who asked him what he had swallowed.

No precise reason can be assigned for

his taking it. His employers state that on the evening before, he had a quarrel with his wife, which might have been the cause of his committing such a rash act; but the wife, on the contrary, denies this, and states that he must have taken it in mistake for some rum; a small quantity of which he was in the habit of drinking, as he himself expressed it, "to cure his lowness of spirits." He had been for some time an out-patient of this hospital, but being greatly relieved, he talked on the morning before he left home of going to the hospital to procure a letter of thanks, for the governor who had given him the admission ticket. It is not known where he took the acid, whether at the place at which he worked, or on his way home: the vial in which it was contained has not yet been found.

*Section cadaveris nine hours after death.*—Body muscular and well formed; old pleuritic adhesions on both sides of the chest, and both lungs adherent to the diaphragm. The heart rather larger than natural, and the left ventricle much hypertrophied. The liver of a dark colour, and the gall bladder greatly distended with bile: it was of a bright yellow colour, except at one spot about three-fourths of an inch in diameter, where it touched the stomach; at this part it was of a green tint. The stomach itself was also much distended, of a dark lead colour, and its vessels full of black blood; the intestinal canal was of the same leaden hue, and its vessels also much engorged with blood. The peritoneum was much injected, and slight depositions of lymph were found throughout the whole peritoneal coat of the alimentary tube. On removing the stomach and oesophagus, and examining them, it was noticed that from the mucous membrane of the latter the epithelium had been removed, and the mucous membrane itself was also injured. The coats of the stomach were much affected, and in many parts nothing but the peritoneal tunic was left: in taking it out it gave way, and about six ounces of a dirty yellow fluid were collected: this coagulated into a solid mass about ten minutes after its removal. The whole internal surface of this viscus was covered with a thick coating, of a yellowish colour, resembling paste, probably caused by the coagulation of the cheesy portion of the milk which was administered, or from other albuminous

matters. Underneath this the whole internal surface was stained of a black colour, in some parts more than at others, presenting a charred appearance: this was most marked near the cardiac and pyloric orifices, and near the great cul-de-sac: this blackening extended also through the duodenum its whole length, especially on the prominent parts of the numerous valvule conniventes, the intervals being stained of a greenish yellow colour by bile, and spots were observed here and there on the jejunum, for about a foot and a half from its commencement.

REMARKS.—On examining the contents of the stomach no trace of muriatic acid could be detected; the fluid that was squeezed from the coagulum gave no indication of acidity when litmus paper was put into it, nor any trace of a chloride when nitrate of silver was added, neither did the distilled water in which a portion of the stomach and duodenum had been boiled. This, I believe, is not unusual, as both Drs. Christison and Beck give examples of this kind, where both sulphuric and nitric acids have been taken, and on examination after death no trace of either has been discovered; but this case would seem more remarkable from the circumstance of muriatic acid being a product of the stomach, either in its natural or diseased state. The fact mentioned above of a portion of the gall bladder being turned green where it came in contact with the stomach, must not be overlooked. I put this in my notes as a thing I had never before seen: it did not strike me at first that the presence of muriatic acid in the stomach might have been, and probably was, the cause of this appearance, and it would be interesting to notice, should another case of poisoning by this acid occur, whether such a change had there taken place.

On my going to this man's employers on the 25th, which was eight days after the melancholy occurrence, I found that they possessed the waistcoat that was stained by his putting the vial into his bosom: this they kindly gave me, and I observed, on that part which corresponded to the left breast, a large stain not of a red colour, as I imagined it would have been, but of a greenish hue: this I touched with my tongue, and by this means could distinctly recognize an

acid taste, the presence of which was further corroborated by my cutting off a piece of the cloth and soaking it in distilled water, when litmus paper was powerfully reddened, and a dense white precipitate was produced with nitrate of silver, which precipitate was soluble in ammonia, insoluble in nitric acid, and presented the other characteristics of chloride of silver—the most important of which, perhaps, is that of being blackened by exposure to light. To satisfy myself that the green colour just now described was produced by muriatic acid, I put some of this liquid about the waistcoat, which I observed was made of black cloth, and on the fourth day after its application I was pleased to find that this also, which was first red, had changed to a green, precisely similar to that portion which was stained by the contents of the vial; which is a fact perhaps worthy of mention. The cloth itself did not appear more rotten at the stained parts than at the unstained.

Your obedient servant,

JOHN QUEKETT,

Medical Student, London Hospital.

Wellclose Square,  
Nov. 7, 1839.

## ON VACCINATION.

DR. GREGORY IN REPLY TO DR. BARON'S  
REPORT.

*To the Editor of the Medical Gazette.*

SIR,

It can be of no importance to your readers what the courtesies of society induced, or the time allotted for discussion, and the hour appointed for dinner, enabled me to say at Liverpool; I am quite prepared to enter on the question, if it should be deemed essential, but otherwise I am unwilling to occupy space and time that may be more profitably employed. But though these be matters of indifference, it is not a matter of indifference whether a report, emanating from an influential body in this country, does really do what it professes to do—give a full and correct statement of the present state of vaccination both with respect to theory and practice. If it does, the discussion of the subject in your widely-circulated columns will add largely to the sphere of its usefulness. If, on the other hand, important circumstances are omitted, conclusions hastily drawn, and facts

imperfectly represented, it is surely desirable that such omissions and inaccuracies, both of fact and argument, should be pointed out. I proceed, therefore, with criticisms on Dr. Baron's report.

The most important doctrine advanced in that report is to be found at page 59, where we read, thus: "We hold it to be proved beyond all doubt, that the same general laws which govern human small-pox apply, *mutatis mutandis*, to cow small-pox. We have a great weight of testimony all entitling us to assert that the cow-pox, duly and efficiently communicated to man, does not lose its influence by time. This opinion, which formerly admitted only of an analogical illustration, has now, by the experiments of Mr. Ceeley, received a direct and positive confirmation." These sentences contain matter for grave reflection. I profess myself unable to see the force of the argument. It confounds common origin with identity. It assumes that because cow-pox can be obtained by inoculating the cow with small-pox matter, therefore cow-pox and small-pox are identical affections governed by the same laws. These two things however, are very different. To give a simple illustration. Calomel and corrosive sublimate have a common origin in chlorine and mercury; but calomel and corrosive sublimate are not identical, and what is true of the one is not true of the other. The agencies of the one cannot be anticipated from knowing the agencies of the other. The mere fact of community of origin does not enable us to predicate that the same laws which govern one agent apply, *mutatis mutandis*, to the other. By passing through the body of the cow, the variolous virus undergoes a great change. It no longer produces fever. It no longer produces eruption. It excites a different kind and degree of local inflammation. The areola of cow-pox is not the areola of small-pox. The purulent tendency of the one is strongly contrasted with the lymphatic effusion of the other. If, then, such remarkable differences exist in the phenomena developed by the direct application of the respective poisons, we are scarcely entitled to reason concerning their ulterior effects, on the assumed principle that the general laws which govern the one apply, *mutatis mutandis*, to the other. It may be true that the security afforded by cow-pox

is fully equal to, or as Dr. Baron seems inclined to admit, superior to that which attaches to small-pox inoculation. It may be true that cow-pox duly communicated does not lose its influence by time; but these important laws must be deduced from an accumulation of facts. They cannot be admitted on the principle that community of origin implies identity of results.

The report concedes (page 59) that the protecting power of cow-pox may disappear, but contends that this is no more than what occurs with those who have had human small-pox. Identity of governing laws requires, however, more than this. It demands that the proportions of those attacked and the rate of mortality should approximate. The experience of the world fully proves that there is no approximation between the numbers attacked by small-pox after vaccination, and the number of those who take small-pox twice. In Dr. Baron's life of Jenner (page 278) it is remarked that, in 1798, when Jenner's discovery was first announced, "it had *escaped* the attention of medical men that small-pox occurred a second time as frequently as it has been proved to do, both by recent experience and past history." Is it not strange that when men's attention was fixed exclusively on small-pox, a circumstance of this importance should have escaped observation, and should only have attracted notice when small-pox was comparatively rare? Is it conceivable that Jenner, who for twenty years had been studying small-pox closely, with an ultimate view to the diffusion of vaccination, should have been so ill informed as to the extent of second attacks of small-pox, as is here supposed; for Dr. Baron admits "that such an impression led to a too confident statement of the never-failing efficacy of vaccination." Is it not more probable that Jenner was correct in his original views of the permanency of the protection afforded by once undergoing small-pox; and that the ardour of his followers in support of vaccination led them to overrate the frequency of recurrent small-pox?

Even the facts adduced in Dr. Baron's report do not bear out his statement. For instance, when noticing the variolous epidemic of Marseilles in 1828 (referred to at p. 65), it is remarked that, out of 30,000 vaccinated persons, 2000 were

attacked with small-pox, of whom 21 died (being in the ratio of 1 in 15 attacked, and one death in 160); while out of 2000 persons who had previously had small-pox, 20 took it a second time, of whom 4 died (being in the ratio of 1 in 100 attacked, and 20 deaths per cent). A difference so strongly marked satisfies me that cow small-pox and human small-pox are not (as Dr. Baron, at page 62. asserts they are) alike in their general properties, but that the laws of cow-pox must be framed independent of all facts and reasonings concerning its origin.

At the Small-Pox Hospital, it is the rarest event to meet with a person who alleges that he had small-pox at an earlier period of life. How is this? twenty such cases are said to have occurred in one year at Marseilles, a town not containing a twelfth part of the population of London. Yet in the severe epidemic of last year, no case of the kind applied for admission into the Small-Pox Hospital. The cases which I have seen in the course of twenty years are too few to enable me to say any thing regarding either the character of the disease, as it occurs a second time, or the intervals that elapse between the two attacks. On the other hand, of cases of small-pox subsequent to cow-pox, I may have seen about 2000, and know pretty accurately the character of the disease as it so occurs, the circumstances under which it occurs, and its average rate of mortality.

Dr. Baron has not laid much stress on the Annual Reports from the Small-Pox Hospital, for reasons which will probably appear in your next number. Whatever those reasons may be (and I dare say they are very good ones), it is satisfactory to me to know that the results of our experience there are corroborated by the least exceptionable authority to which we can refer in this country. Dr. Baron (at page 81 of his report) states that he has been favoured with some communication from Sir James Mc-Grigor, but he does not give its exact import. I have lately had an opportunity of perusing the returns, exhibiting the amount and character of the small-pox, occurring after vaccination, in the British army on home service, for the five years ending Dec. 31, 1838. I have reason to know that a similar return from the British army on foreign service is now preparing, and

that instructions have been issued for extending the reports to Dec. 31, 1839. When completed, these documents must necessarily prove very valuable. There can here be no cavil about the reality of the preceding vaccination, because the attention bestowed upon every recruit entering the British army, and on every soldier's child, with reference to vaccination, is excessively strict, and leaves nothing to be desired. I have not received Sir James M'Grigor's permission to publish, *in extenso*, that portion of the return which is now completed; but I may be allowed to say that it fully bears out the four great statistical principles deducible from the experience of the Small-Pox Hospital,

which are—1, That, on an average, out of every 100 cases of small-pox occurring after vaccination, 60 are mild and modified, 40 confluent and severe. 2. That the mortality in these 40 cases follows the usual law of the casual small-pox, without reference to prior vaccination. As a consequence, 3dly, that the average mortality of small-pox, after vaccination, is 10 per cent., varying between 7 and 12. 4. That the disposition to receive small-pox after vaccination is greater in adults than in children.

In the annexed table I have indicated enough to shew the singular coincidence between the results of civil and military practice, in reference to small-pox.

*Table exhibiting the character of small-pox (with the rate of mortality), as it occurred in 1838, to vaccinated persons in civil and military life.*

	Total Number.	Distinct & Modified Cases.	Confluent Cases.	Deaths.	Rate of Mortality.
Cases occurring in the British army on home service, in 1838.....	237	153	84	29	12 per cent.
Cases occurring at the Small-pox Hospital, in London, in 1838.....	298	190	98	31	10 per cent.

Dr. Baron (in his report, page 61) lays down the maxim "that all cases of reputed vaccination should be considered as no vaccinations at all, unless they have passed under the review of a competent judge, who has witnessed the different stages of the affection." I presume that Dr. Baron's implied meaning is, "who has witnessed the different stages of the affection," and pronounced it to be regular; but when laying down what he calls "a canon to be universally admitted and acted upon," that very important clause should have been inserted. The canon is good in theory, but wholly inapplicable in practice. In the case of an individual attacked 25 years after reputed vaccination, how is the medical man to ascertain whether his patient passed, during the process of vaccination, under the review of a judge? how is he to know what decision that judge came to, and whether he was competent or not to form such a decision? On a large scale the thing is quite impracticable. In all countries, therefore, the test chiefly trusted to is the character of the cicatrix. On the value of this

test the report speaks very doubtfully. Dr. Baron intimates (page 33) that even if quite normal "it ought not absolutely to be trusted to," while all irregularities, and still more "the absence of a cicatrix, must be held to speak strongly against the existence of vaccine influence." There is not here much to object to, but I question whether this expresses all, in reference to the cicatrix, which may fairly be deduced from the facts now before the world. It appears to me, 1, that a perfect cicatrix is in itself a satisfactory proof that the individual has passed through regular cow-pox, and has derived from it all the protection which it is capable of giving. 2. That irregular cicatrices are compatible with full constitutional influence, because it so often happens that irregularities to the vesicle commence incidentally after the tenth day, when we may reasonably presume that the specific constitutional effect has been produced. 3. That the absence of a cicatrix is not decisive against either the present or prior existence of vaccine energy in the system, because, in many cases, the specific

inflammation is moderate, and the resulting scar wears out in the progress of life, as other scars do which are not the results of a specific poison.

I would next wish to direct the attention of Dr. Baron, Mr. Goolden, and others, to the following important principle,—that if so much nicety is required before we can safely pronounce that vaccination has preceded any given case of small-pox, so in like manner should it be a canon with all medical men not to admit any case to be one of recurrent or secondary small-pox, “unless the first attack passed under the review of a competent judge, who witnessed the different stages of the affection,” and pronounced it to be true small-pox. From my situation at the Small-Pox Hospital, I have been called upon to witness many cases of supposed secondary small-pox. Repeatedly have I found some error in diagnosis. In one case it was secondary syphilis; in another febrile lichen; in a third it was *porrigo favosa*. In a still larger proportion of cases, I convinced myself, by inquiring into dates, that the first attack was not variolous. The diagnosis between varicella and variola is at times very difficult, and even a “competent” judge may be deceived. If Dr. Baron’s vaccine canon “were universally admitted and acted on,” with reference to secondary small-pox, the number of such cases would, I apprehend, be very materially abridged.

I have still in reserve a few observations on that part of Dr. Baron’s report which alludes to the advances in vaccine pathology made since the publication of Jenner’s “Inquiry.” These, if you will spare me room, shall form the subject of my concluding communication.

I am sir,

Your obedient servant,

GEORGE GREGORY.

31, Weymouth Street,  
Nov. 9th, 1839.

## FLUORIC ACID IN ANIMALS.

*To the Editor of the Medical Gazette.*

SIR,

In the last number of Guy’s Hospital Reports there is an article by Dr. Rees, on the supposed existence of fluoric acid as an ingredient in certain animal matters, and after various experiments, he comes to the conclusion, “that the

fluoride of calcium should be expunged from the list of the constituents of animal substances.” With all due deference to so high an authority, I must beg leave to relate a circumstance which, if the corrosion of glass is a sure test for fluoric acid, appears to me sufficient evidence of its presence in animal substances.

Being engaged on the teeth, I had the recent skull of a horse brought me: I extracted the teeth, and washed them, and for want of some other vessel, put them in a glass vase which stood in my room, and filled the vase with clear water, with the intention of procuring them clean; several weeks elapsed before I wanted to use them, when on turning them out and washing the vase, I was surprised to see it superficially corroded as high as the water had been. Now as this had not been exposed to any heat beyond the common temperature of the atmosphere, the corrosion could not be attributed to *phosphoric acid*.

Trusting that the love of truth will be a sufficient apology for troubling you,

I remain, Sir,

Your obedient servant,

LOTA.

Bath United Hospital,  
Nov. 1839.

## MEDICAL GAZETTE.

*Friday, November 15, 1839.*

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

## WORK GRATIS.

It has from time to time been our painful but useful office to draw the attention of parents to the excessive competition which exists in our profession. At one time we told them of a surgeon who attends a factory in Lancashire containing 1173 men, for six guineas a year\*; on another occasion we pointed out an advertisement for “an humble young lad,” whose references were to be good, and who was wanted to officiate gratuitously as a medical assistant†.

\* MED. GAZ. vol. XX. p. 243.

† Ibid. vol. XXI. p. 928.

In the same article we gave the curious case of the Suffolk curate who practises physic for most slender fees, and on the charge being brought against him, retorts upon the accusing surgeon, that *he* used to bleed and draw teeth at sixpence a head. We, too, were the first to comment on that remarkable announcement in the *Times*, that a member of the medical profession would have no objection to perform the duties of valet\*.

These facts are unfortunately very far from unique, as any one may know who gazes on the permutations and combinations of society as they are mirrored in the advertisements of our daily newspapers. Indeed, the race of practitioners who desire to have their work done gratis will naturally increase, as long as the wild rush of hungry and mistaken persons into our profession shall continue. If they cannot get a bellyful *plus* wages, they will accept the former alone, or in time may take places where the rations are dealt out according to the principles of Assistant-Commissioner Mott.

Here is a situation for those who like to work gratis:—

“Wanted immediately, by a general practitioner at the west end, a young man accustomed to retail, as assistant. He must be able to prescribe, if required. None whose moral character will not bear the strictest inquiry need apply. The advantages are such that no salary will at first be given. Apply,” &c.—*Times*, Oct. 24, 1839.

Or, here is another, more exacting still.

“Wanted, immediately, an humble and well-conducted young man who understands retail, and can prescribe over the counter when required. A comfortable home and other advantages will be considered equivalent to a salary in the first instance. The best reference will be required. Apply,” &c.—*Times*, Nov. 7, 1839.

The parent who studies the signs of the times, will pause when he sees these advertisements; and if his means are scanty, and he had proposed to spend a hundred and fifty or two hundred pounds on the education of his son, without additional capital to push him on when his apprenticeship is completed, he will do more than pause,—he will give up his rash intention.

Observe, too, that it is not a mere shopman that is asked for by either practitioner, but an assistant who can prescribe; one, in short, who joins the talents of a physician to the unwearied industry of a medical drudge. If, by prescribing, the advertisers mean prescribing accurately in writing, we should say that the combination is not met with every day; nevertheless, they may get it, for there is a glut in the market, and ability, medical ability that is to say, is a drug. After all, the employers will reply, “the work is not absolutely gratis; shelter from the weather, and a share of our family mutton and potatoes, must reckon for something.” Why, yes; let us be candid; even an assistant’s fraction of the most *modeste dîner* must reckon for something, though for wonderfully little. He lives, in too many cases, “a man forbid,” and must not cry “*repetatur!*” even to the *cyathus theæ*.

But then, both advertisers promise “advantages.” However skilful the two assistants may be on entering their service, their skill will be polished up to a still higher pitch of perfection; in short, the more they work, the more they will know. True; but the same advantages would result from gratuitous work in other trades, where such a demand is rarely, if ever made. If the young engineer, on the completion of his apprenticeship, would toil for his meals alone on board the Starlight steamer, he might ultimately get a better engagement on board the Laurel; but in his

\* *MED. GAZ.* vol. xxiv. p. 349.

more fortunate profession this is not necessary, and those who know their business are paid for exercising it.

Remark, again, that both the advertisers profess to give no salary at first; thereby intimating that a happier day may come at last, when their medical servants shall pocket a few pounds. But, sooth to say, these places, where there are no wages at first, always remind us of an instructive anecdote which we read many years ago. An Irishman being desirous to learn to play on the flute, applied to a professor of the art, and asked his terms, which turned out to be two guineas the first month, and a guinea the second; "Oh! then," exclaimed the pupil from the sister island, "I'll learn the second month." Now we are apt to imagine, perhaps too uncharitably, that at places like those we are criticizing, the reverse will be the case, and the unfortunate assistants will find nothing but first months.

One of the advertisers, besides gratuitous services, demands humility. This is probably the same practitioner whose wishes we noted in March 1838, and who then merely asked for "an humble young lad," but now, grown bolder by time, requires "an humble and well-conducted young man." It is probable enough, that in such a situation the lad or man will have an opportunity of learning not only humility (should he bring an insufficient stock with him) but two other cardinal virtues—temperance and fortitude.

It is touching upon a subject almost too trite for mention, if we add that gratuitous labour is not confined to the lower walks of the profession, but is equally required from the highest. In the matter of charitable institutions, as every one knows, there is not only a struggle among competitors eager to do the work for nothing, but considerable sums are often expended to attain the wished-for zero. "Ay, but they do

this to get known," is the ready-made explanation. Likely enough; but in other employments people "get known" without this long quarantine. If a man were to paint portraits gratis for five years, it might ultimately procure him some monied customers; but the limners are not driven to this.

Surely the parties interested will in time open their eyes, and acknowledge that the constant struggle to be allowed to toil for nothing in our profession, is a proof of greater competition in it than can exist in those happier occupations where labour meets with its reward.

It is certain that in every age, as one employment falls into disuse, or becomes less lucrative, some other springs up, or requires a larger number of hands. The profession of engineer seems to be one which in our time has suddenly opened its portals to let in a crowd of applicants, and still has room for more. Whether we understand by engineer the great thinkers, the Telfords and the Brunels, who change the face of a country, and annihilate space and time; or those humbler aspirants to bread and occupation, who watch the motions of those machines which genius has created; in either case, the demand seems at present greater than the supply, and we do not hear in those quarters the dispiriting cry of the profession being overstocked.

But this we leave to individual consideration. The parent who clearly sees that he ought not to bring up his son to be a medical assistant will find some preferable employment; the negative will soon lead to the positive. Every one will confess that salaries varying from nothing up to forty pounds a year are no great bait, but rather make one admire the frank good sense of the "member of the medical profession," who desired last May to become a valet. But as hope is always at the bottom of the largest box, even of medical evils,

some one will ask, may not my boy rise from his professional serfdom to some free and distinguished post? Did not Dubois come to Paris with two sous and a half in his pocket, support himself by copying law-papers, and teaching reading and writing, and finally rise to the highest eminence as a surgeon\*? He did; and so may others, with the same superhuman industry. But for one such instance there are a thousand where the unfortunate victim of his own or his parents' vanity drags on a wretched servitude thinly disguised under the name of a liberal profession. Experience teaches us not to take every sharp lad to be an unexpanded Dubois, on the testimony of his father or his aunt. In doubtful cases it will be safer to make him engineer on board the Starlight.

#### NON-MEDICAL QUACKS.

WE have often had occasion to call the attention of our readers to the unblushing effrontery of medical quacks, and we also think it right to bring under their notice advertising quacks of another description, to caution them against the possibility of their names being paraded before the public without their knowledge or consent, and in a manner most injurious to their interests. The professors of medicine are of all scientific persons most obnoxious to this annoyance—articles of food, wearing apparel, carriages, almost all the necessities, and many of the luxuries of life, are now dignified with medical certificates. No new-fashioned stay is ushered from the hands of the *artiste* without a testimonial of its invaluable properties; no bandage, truss, or instrument intended to relieve any defect, obtrudes itself upon society unaccompanied by a string of medical names, extolling its good qualities. The system has now arrived at such a pitch, that it

has become an intolerable nuisance. The opinions of eminent medical men are sought for the purpose of private advantage to the speculator, and often obtained, the party granting the certificate not being at all aware what use it may be put to. We do not mean to infer that those certificates are given without a conscientious belief in the truth of what is averred, but we mean to say that in nineteen cases out of twenty, when a medical practitioner or other man of science is applied to for such a purpose, he would rather withhold than grant it. He grants it believing in its correctness, perhaps to get rid of importunities which are annoying to him, perhaps out of a good-natured desire to oblige the advertiser, or more frequently some friend who has introduced him.

The certificate thus got hold of turns out a mine of wealth to its possessor. At first he only shews it to his customers, as most likely he has made a sort of promise that it should not be published; next he prints it in the form of a circular, and distributes a copy of it with every article he sells; afterwards he rises higher in his flight, and advertises it in the newspapers: nor, indeed, will he stop here, but in many instances garbles it—suppresses some parts, adds to others, inserts the superlatives “most,” “very,” “exceedingly,” “unquestionably,” &c. &c. to suit his own purposes. Indeed, instances are not few, where whole letters have been written by the advertiser, and signed with the name of the gentleman who has unwarily given the sanction of a general testimonial, not one word of which letters did the person whose name it bears ever pen, and from many of the sentiments contained in which he entirely dissents.

We have been led into these remarks by an occurrence which happened last week. There is a firm, carrying on business as spectacle-makers, in Alb-

\* MED. GAZ. Vol. XX. p. 87.

marle-Street and Cheapside, under the name of Solomons. These people are daily advertising in the principal newspapers. They persuaded some gentlemen connected with medicine to sign a general testimonial in favour of their lenses, and others to give them a particular certificate: among the former is Dr. Francis Ramsbotham, who, having known the parties many years, and having made trial of the spectacles, was, we understand, induced, by their solicitations, to give his signature. After the lapse of about a year, there appeared, in a number of the papers of the day, a letter purporting to have been sent by Dr. Ramsbotham to Messrs. Solomons, signed with his name and dated from his residence, containing the most disgusting nonsense that ever was put on paper. This testimonial was, in fact, a complete fabrication; yet the parties unhesitatingly acknowledge their intention of substituting another name, as Dr. Ramsbotham is so fastidious. In a letter addressed to him, which he has forwarded to us, they very coolly say—"Now, sir, if you wish to have your name withdrawn altogether, we have not the least desire to use it, as we have a great many other medical gentlemen, of high character and reputation, which we cannot \* used, and we can place one of them in your place." We trust that any one whose name is thus substituted will take legal steps against the parties.

### DEATHS BY POISON.

THE "Gateshead Observer," of Nov. 2, contains a very important and interesting document on the subject of poisoning, which we subjoin.

We have before us a Report made to the House of Commons at the instance of Sir Robert Inglis, and ordered to be printed on the 27th of August in the present year. It is entitled, "Returns from the Coroners of England and

Wales of all Inquisitions held by them during the years 1837 and 1838, in Cases where Death was found, by verdict of Jury, to have been caused by Poison." This Report is fraught with deep and melancholy interest; and considering that the public may be benefited by an extended publication of its contents, we have with considerable care and labour reduced the Returns into a compact and popular shape, to adapt them to our columns.

We regret, first, that the Returns are not complete, some Coroners having neglected to comply with the request of the Commons; and, second, that the Coroners who have made Returns, have, in many instances, omitted particulars of great moment. We have endeavoured, however, to make the best of the imperfect materials before us.

We have classed the deaths under the various descriptions of poison by which they were caused:—

<i>Arsenic</i> .....	184
Taken by a girl disappointed in love .....	1
By a girl, in a fit of passion .....	1
By a girl, in a fit of jealousy ...	1
By a girl who had robbed her master's son .....	1
By a girl, seduced and deserted by a married man .....	1
By a girl, subject to fits and despondency .....	1
By pregnant girls, to destroy themselves .....	5
By a pregnant girl, to procure abortion .....	1
By a pregnant girl, deserted by her lover, who was suspected to have procured her the poison ...	1
By a pregnant girl—how or by whom administered not known ..	1
By a wife, separated from her husband .....	1
By a young woman, married unhappily, and separated from her husband .....	1
By a cook-maid, distressed by the death of a friend .....	1
By an insane mother and two children—administered by the former .....	3
By five children, to whom it was administered by an insane mother ..	5
By a man, embarrassed by debt, and disordered in mind and body ..	1
By men, through reduced circumstances, pecuniary embarrassments, &c. ....	6
Taken through drunkenness .....	12
By a farmer and innkeeper, who, having had a handsome legacy left to him, spent it in riotous living—got intodetb—and took poison to escape his creditors ...	1

543

The total number of deaths by poison, in 1837 and 1838, it will be seen, was 543. Of these 261 were females; 282 males.

The total number of individuals poisoned by opium, or its preparations, was 186.

The deaths of very young children (most of them at the breast), from opium, or its preparations, administered by mothers and nurses, in ignorance of the powerful effects of those substances on infants, were 52.

The deaths of young children from opium or laudanum administered in mistake for other medicine, were 20. In 11 of these cases, the names of the medicines are given, in the place of which opiates were given by mistake.

*The very great number of deaths amongst children, resulting from overdoses of opium, or its preparations, and from doses thereof given in mistake for other medicines, cannot fail to excite attention. Deaths of this kind amount nearly to a seventh of the entire number of deaths by poison! The number was 72!*

Most of the children poisoned in this way *lost their lives* owing to the ignorance, carelessness, or presumption of *their mothers*. It cannot be too generally known that narcotic and anodyne drugs, powerful though they be in the adult, act with infinitely greater energy upon the more sensitive nervous system of the infant; so that even experienced medical men never administer remedies of this class to the very young, without exerting the utmost caution and making the most accurate calculation. Two drops of laudanum have been known to kill an infant. Nay, we have heard of a case in which *one drop* stole away the life of a new born

babe. It is evident that the practical inference to be deduced from the facts represented in the above table is—that *mothers and nurses should never dare to administer medicines of the narcotic kind, except under the immediate direction of the medical attendant.*

The Coroner of Nottingham states, that “Godfrey’s Cordial is given to children to a great extent; and that he has no doubt whatever, that many infants are yearly destroyed in that borough, but who, dying off gradually, never come under his notice officially.” There can be no doubt of the truth of this assertion. At all events we can say positively that such instances occur elsewhere.

It will be observed, that of the 20 cases in which death resulted from the administering of opium or laudanum by mistake, 11 were instances in which they were given instead of substances more or less resembling them in colour. No details of the mistakes are given in the remaining 9.

In recording one of the 11 cases, Mr. Browne, the Nottingham Coroner, (who has very commendably entered more into detail than most of the Coroners,) says: —“There appeared very great negligence on the part of the person who sold the laudanum. He had not been brought up as a druggist, but had latterly taken to the business, and employed two young girls to attend to his shop, and sell his drugs in his absence. I ascertained, personally, at the shop, that one of them sold twice as much for a penny as the other!”

In 10 of the 11 cases, although the medicines are named instead of which laudanum was administered, we are not told whether the mistake was made by the mother, the medical attendant, or the dispenser.

We find in the returns 4 cases of the administration of savine and other poisonous drugs, with the view of procuring abortion. In 3 of these cases, the mother perished undelivered. In the fourth, the child perished.

We believe the disgusting crime of fœticide would not be so often attempted, if the real effects of savine, and the other drugs made use of, were properly understood. These agents never can induce abortion without placing the woman’s life in the greatest danger; and a very frequent result is, that she dies undelivered, having previously suffered the intensest agony.

In 8 cases, poison was taken for the purpose of self-destruction, by young women who had been seduced and were pregnant. Arsenic was the poison made use of in all these instances. It is probable, that besides these 8 cases, several

other of the numerous instances of poisoning by arsenic had been the result of seduction;—but this is not stated in the Returns, which, we repeat, are very far from being full and satisfactory.

The deaths of 8 surgeons are entered, and it is a curious circumstance, that all of these had taken prussic acid. One had taken it with arsenic. Three committed self-destruction in consequence of pecuniary difficulties—one the during delirium of scarlet fever—one during the delirium of mania *a potu*—three during insanity. No instances of poisoning among members of the other learned profession are stated. *Perhaps* this may be owing to an omission in the Returns—but we are rather inclined to consider that they are not defective on this point.

Do not these facts furnish medical men with materials for melancholy reflection? Eight of their brethren have, within a short period, destroyed themselves; whilst no other profession is named on the tables. Three of these, indubitably, were urged to the rash act by embarrassments; and four committed suicide in insanity, which was probably induced by long-continued anxiety and disappointment. In one case only—that of insanity following scarlet fever—could different and natural causes be assigned. May not these instances of self-destruction be deemed indications of an overstocked and ill-regulated profession?

These important Returns would furnish us with the means of extending our remarks to a much greater length, but we must—for the present at least—forebear. We cannot, however, conclude, without expressing our approval of a valuable suggestion made by Dr. Frampton, Coroner for Dorsetshire. This gentleman thinks there should be some way of *compelling* those who sell poison to *register* the day and the hour of sale, and the name of the purchaser. Mr. Frampton justly observes that from a want of such compulsory registration, the ends of justice are frequently frustrated.

Great credit is due to Sir Robert Inglis for having called for these Returns. They would, however, be much more useful to medical and political science, had information been required as to the profession, trade, or station in life, of each individual; and if it had also been stated (whenever possible) how the poison had been procured—whether from a druggist, a surgeon, or otherwise—the quantity sold, the age of the dispenser, and whether any precautions had been taken by him to prevent mistakes.

## PHYSIOLOGICAL AND ANATOMICAL OBSERVATIONS ON A BEHEADED CRIMINAL.

By DR. T. L. W. BISCHOFF,

Professor at Heidelberg.

SEBASTIAN ZINK, a robber and murderer, was executed at Rastadt, July 6th, 1838. My friends and colleagues, Drs. Heermann and Jolly, and myself, resolved to take advantage of this opportunity, and bring several scientific questions nearer to their solution, if possible, and thus, to the best of our powers, make the public profit by an event for which every philanthropist must sorrow.

Notwithstanding what has been already published on the subject, it appeared to us an important problem to ascertain whether consciousness remained in the head, after its separation from the body. There is an accurate and critical memoir on this subject, by Nasse the elder, in his “Physiological and Pathological Investigations,” Bonn, 1835, 11ft. 1, p. 25. Every question belonging to this point is there examined in the most accurate manner, and as the essay brings together every observation of the kind hitherto made, it has served me as a point from which to consider future experiments, while it saves the necessity of going into the earlier cases. Nearly at the same time, Phöbus, in *Hitzig's Annalen*, Hft. xxxiii. p. 175, and in the Berlin Encyclopædic Dictionary of the Medical Sciences, collected all that was most important on this subject. He there asserts his belief somewhat too hastily, that farther observations of the kind are unnecessary, and therefore should not be allowed. To me it seems that the mode of action of the nervous energy, and its union with the powers of the soul, is far from being so thoroughly understood. In fact, of late years the theory of this subject has taken so different a turn, that new experiments appear to me especially requisite. For, with the exception that human beings can communicate the sensations which they experience, the phenomena from which we believe that we can infer the presence of psychological activity and consciousness in other beings, are for the most part merely motions, which are occasioned by external influences. As these movements seem to be proportioned to the external influences, we believe that they are caused by certain sensations, and that they bear the character of free will and of design, and therefore that they are evidence of psychological energy. But now that we have

recently learned with more exactness the mechanism, so to call it, of the nervous energy, and have thus been made more attentive to the reflex movements, the question is more difficult to answer, and the problem has to be almost entirely worked through again, with reference to the manifestations of psychological energy and animation. For we have convinced ourselves that there are many movements bearing the character of design, and therefore presupposing free-will, where we are yet not justified in assuming a real co-operation of the soul in feeling and willing; but which are rather excited without any affection of the soul, by the transference of the irritation of a nerve conducting to the centre, to a muscular nerve conducting to the periphery. But the question whether a single movement or whole classes of them have this or the other character, is the more difficult to answer, as the same movement may depend on either cause, being at one time psychological, and at another only a reflex movement.

This point is of particular importance in the question concerning the continuance of consciousness in the decollated head. For, in the way in which the majority of experiments have hitherto been performed, it might easily happen that most of the movements perceived in heads just separated, had not this character, but were merely reflex movements. I therefore resolved first of all to avoid the application of all stimuli, from which such a reflected effect might be readily expected, and as much as possible to excite the organs of the senses by those irritants, from which this was less to be feared.

The fatal stroke of the sword took place at thirty-six minutes and a half past nine, and a few moments afterwards we received the head, which was handed to us in the mask which surrounded it, without its having been shaken by a fall. The first step was to free it quickly from its mask, and observe the manner of its separation from the trunk, the hemorrhage, and the expression of the features.

The stroke had succeeded perfectly, penetrating in front between the os hyoides and the larynx, and posteriorly between the fourth and fifth vertebræ, but so that a part of the left oblique process and of the body of the fourth and a part of the oblique process of the fifth vertebræ were cut through. The blood flowed out slowly, but uninterruptedly. The expression of the countenance was that of the most perfect repose; no trace was there of pain or distortion. The eyelids had somewhat sunk; the mouth was shut, but easy to

open. The expression of the eyes, too, was perfectly tranquil; neither wild, as given by one of the earlier observers, nor wan and lustreless, but like that of one who is gazing upon the distance. Dr. Heermann, who had visited the criminal for an hour the preceding evening, thought that he saw no alteration of the features, except in the loss of the man's sharp and piercing look, and the pupil being somewhat larger.

I now brought my fingers, and then a bright needle, near the eyes, without touching either of them or the eyelashes. But though this was repeated several times it was not followed by any trace of motion in the eye, or lids, or any of the features. Dr. Heermann standing at his left side now shouted his name into his ear, and the word *Gnade*, (pardon) with the just conviction that this word would be the readiest to act on any remaining consciousness, as from the whole deportment of the criminal up to the last moment before his execution, it was clear that he had always hoped for mercy. But no trace of motion followed. I now held a phial with a strong tincture of assafoetida to his nose, preferring this to ammonia, and the like, because I expected a more unmingled effect upon the nerves of smell from it than from ammonia, which might possibly produce a reflex motion by irritation of the nerves of the mucous membrane. But this experiment likewise had no result. I next put a drop of tincture of colocynth on his tongue, and on this there was a slight protrusion of the tongue, and a slight movement of the jaw. Both occurred three or four times with short intervals, though no alteration or motion was to be perceived in the other features. In order to judge in some measure how much of these movements was to be attributed to the irritation of the nerves of the mucous membrane by the spirit of wine in the tincture, I put a drop of pure spirit on his tongue, on which there was equally a movement of the tongue and jaw. All these experiments were completed in less than a minute after the fatal stroke. It may be asked, whether these slight movements of the tongue and jaw were the result of sensation, and therefore of consciousness; or whether they were reflex movements, depending on the irritation of the nerves of the mucous membrane; or lastly, whether they depended on the irritation of the divided spinal marrow, and were therefore not caused by the tincture of colocynth. To us observers the last seemed the most probable supposition. The continued tranquillity of all the other muscles of the face did not seem to be in favour of these motions being caused by a disagreeable taste.

Reflex phenomena, indeed, occur very extensively in the movements of mastication and deglutition, but much less frequently in irritations which affect the tongue than in those which affect the mucous membrane of the palate, the velum palati and the pharynx. Moreover, I shall soon have to mention, that when the nerves of the mucous membrane of the tongue were actually irritated with the point of a needle, no motion followed. On the other hand, opening and shutting of the mouth are movements which one has had the most frequent opportunity of observing in decapitated beasts, and which certainly depend on violent irritation of the spinal marrow. The tongue, too, must necessarily share in the movements, from the *os hyoides* having lost the muscles which depress it.

Thus, not a single phenomenon appears to have been present which could lead us to suppose that consciousness still continued; it seemed to have been instantaneously taken away. It is to be remarked, too, that the criminal was not in an unconscious state before the stroke; though, according to Heim, Brand, the Berlin executioner, believed this to be the case in the majority of the ten criminals whom he had executed. Zink, indeed, before his execution, was in an ungovernable and somewhat intoxicated state, suiting the sombre roughness of his whole character; but so far was he from having lost his consciousness, that when the hangman's assistants were putting on his mask, the very moment before the fatal blow, he said to them "you treat one like the flayers."

During life, as well as in the experiments after its termination, he appeared like a man of very little nervous irritability or activity, so that the opposite observations of others cannot be invalidated by this case. Yet I would add, that the negative results of an observer in a frame of mind like that of most persons at such a moment, are in themselves more credible than positive ones; for in the latter, the excited fancy may often act a considerable part, as appeared from the narratives of many who were present at this execution, and who asserted that they had seen wonderful things on similar occasions formerly. It also appears from an accurate criticism of the testimony of other persons in favour of the continuance of consciousness, that there are but few of the experiments made upon the organ of hearing, and upon irritated beasts, which cannot be explained by the supposition of their being reflex motions, or caused by the irritation of the spinal marrow.

After we had made these observations, I immediately performed irritations, in

which I expected genuine reflex motions. I touched, therefore, with a needle, the eyelids and lashes, as well as the conjunctiva of the eye; I irritated the mucous membrane of the nose, mouth, and throat, in the expectation of seeing some movement produced; but all in vain; all the muscles remained perfectly tranquil, which was a further proof of the rapid disappearance not only of consciousness, but also of nervous irritability. Even inserting the needle into the divided spinal cord at the end belonging to the head, and touching it with a piece of caustic potash, produced no movement in the head, and yet no more than from two to three minutes had elapsed since decapitation.

We now turned to the trunk, and while Dr. Heermann quickly tied the carotids, from which blood continued to flow in small jets, in order by keeping in the blood to maintain the irritability of the muscles and nerves, I endeavoured by pricking, scratching, and pinching the skin of the soles, toes, and fingers, to excite reflex motions, but in vain. Immediate irritation of the spinal marrow was followed by convulsions in the pectoral muscles, and lifting of the arms. The corpse was now put into a box, and taken with the utmost dispatch into the neighbouring hospital, where every thing was prepared for further experiments. Still it was now a quarter past 10, and therefore 38½ minutes since the beheading.

We next intended to try experiments on the supposed presence of electrical currents in the nerves. For this purpose Dr. Jolly had prepared a Nobili's galvanometer of the most extreme sensibility, which, for example, shows a deviation of the magnetic needle to the amount of 90°, when a copper plate of a quarter of a square inch in superficies is dipped into pure water. I now took the two conducting wires terminating in platinum needles, and plunged one of them into the grey and the other into the white substance of the spinal marrow. But in spite of the repetition of this process there was not the slightest deviation of the magnetic needle; but it must be mentioned that the introduction of the needles did not even cause any convulsions of the muscles. Folchi says that when he tried a similar experiment on the spinal marrow of a decapitated calf, he observed a deviation of the magnetic needle 6° to the W., at each introduction of the needles (compare Froriep's Not., No. 950.); but I have frequently tried it on decapitated dogs without any result. Meantime, Dr. Heermann exposed the median nerve in the upper arm, and I plunged both needles, at the distance of about an inch, into the trunk of the nerve, and endeavoured by

mechanical irritation of the spinal cord to produce convulsions in the arm; but they did not occur, nor any deviation of the magnetic needle. Having a powerful galvanic pile consisting of sixty pair of plates, each of four square inches, which gave me a pretty brisk shock, afforded sparks, and strongly decomposed water, I now directed one pole to the spine, and the other to the hand. Evident but slight convulsions were produced in several muscles of the fore-arm and humerus, namely the supinator longus, the extensor carpi ulnaris longus, and the inner head of the triceps, but no deviation of the magnetic needle. It remained quite motionless, even when I applied the second pole to the nervous trunk itself; nay, even when I applied both poles to the nervous trunk, in such a way that the circle was completed by the nerve and the needles sticking in it; although every time convulsions were excited in the muscles above mentioned. Though nothing can be deduced from this in favour of the hypothesis of electrical currents in the nerves, yet it seems to result that the nerves are remarkably good conductors for electricity, and even better than the metals, as otherwise one cannot see why the magnetic needle did not deviate, if the metal wires had been the better conductors.

Mechanic irritation of the median nerve, pricking, pinching, and even dividing it, now no longer had any effect, while galvanism still excited convulsions.

I now opened the thorax and abdomen, while Dr. Heermann tried some experiments on the irritability of the iris. It was then ten minutes to eleven, and the iris could no longer be made to contract, even when the polar wires of the pile were brought into contact with it after removing the cornea. Yet the pile was so strong that decomposition of the humours of the eye, and development of gas, immediately followed.

No spontaneous movements were to be observed in the thorax or abdomen; and when the galvanic pile was applied in succession to the phrenic and vagus nerves, to the stomach and intestinal canal, to the ureters, the gall-bladder, and the cystic duct, no contractions were produced. Only the right auricle of the heart was made to contract continuously until a quarter past one; and also the other muscles of voluntary motion, in which, however, at 10 minutes to 1 these contractions were hardly perceptible any longer. As the experiments upon the phrenic nerve and nervus vagus were made at 10 minutes past 11, and therefore only 1 hour and 33½ minutes after decapitation, and the convulsions of the muscles of voluntary motion were also

slight compared with those described by other observers, what I said before when speaking of the head is confirmed, namely, that the irritability and activity of the nerves in this subject were not very much developed. Meantime, I had found the thoracic duct with some trouble, as the body was very fat, and the duct contained no white fluid, but only a turbid and greyish one. Some of it was taken out, and coagulated as usual, but only a very slight fibrinous coagulum formed upon the rod which stirred it up.

After the chyle I examined the mucous membrane of the trachea and larynx, and had the pleasure of seeing the ciliary motions myself, and being able to show them to the bystanders. They were not visible in the œsophagus, not even in that part of the mucous membrane which covers the posterior side of the annular cartilage.

I then examined the urethra, the vesiculæ seminales, the vas deferens, the epididymis, and the testes. In the urethra there were clear traces of an ejaculation, (as in the case observed by Valentin, *Repertorium* 1, p. 277.) caused, of course, by the violent contraction of all the muscles at the moment of decapitation. In the urethra were several large gelatinous coagula, looking exactly like coagulated fibrin, and a whitish fluid containing numerous seminal animalculæ, though not so numerous as I had observed them in the genital fluid of many animals. In the vesiculæ seminales, which were not very large, there was the same sort of gelatinous mass, and also seminal animalculæ. I found them alive in the whole vas deferens as far as the testes, but not very numerous. I thought that I found them also in the seminal ducts of the testes, but as they were very few, and no longer living, I cannot be sure of it. Moreover, the contents of all the parts just named included several other kinds of little particles, but none of such distinct forms as Valentin gives. They were most probably only particles of epithelium. A clear and transparent fluid was collected by dividing the prostate, but I could not observe any elementary particles in it, except some corpuscles of the blood. I then took great pains in examining the brain. As soon as Dr. Heermann had opened the skull, the vessels were seen to be filled with air, and, moreover, the air had everywhere penetrated between the pia mater and the arachnoid, so that the upper surface of the hemispheres had got a very peculiar appearance. Had the air entered from the spot where the spinal marrow was divided? This is difficult to believe, for, in the spinal marrow as in

the brain, pia mater and arachnoid lie pretty close to one another, and there is no fluid between them to make room for air by its evacuation. Did it enter by laceration of the vessels? This, too, I am unable to suppose. This confirms my view, that the course and form of the arachnoid are not yet rightly made out. Of the microscopic examination of the substance of the brain, I will here merely say, without anticipating farther observations, that after the examination of many dogs' brains not only fresh, but actually warm, I cannot agree with Ehrenberg and Valentin, and that I think the microscopic structure of the brain by no means made out. The varicose tubes I believe to be certainly the effect of pressure; but the matter is not so simple as it is represented by Valentin. Amid the multitude of objects calling for attention I unfortunately omitted to look for ciliary motions in the ventricles. I paid particular attention to the spleen. I found in it those small white points, (the corpuscles of Malpighi) which I have seen only in the spleen of animals of the four classes of vertebrated animals.

Lastly, I examined the stomach and the villi of the small intestines microscopically. In the former it was remarkable that the mucous membrane of the fundus was already almost entirely dissolved; it was four o'clock in the afternoon, and very hot weather; the contents of the stomach were wine and salad, and very sour. The villi of the small intestine were pyramidal in shape and composed of granules. Neither in them, nor in the mucous membrane of the stomach, after I had gently rinsed them in water, could I perceive any epithelium.

No morbid appearance was to be found in the whole body, except an adhesion of the lungs to the parietes of the chest, probably caused by a shot-wound under the third rib: three large shot, quite unaltered, were lying in different places loosely surrounded by cellular substance, under the pleura costalis. The heart, indeed, had a very strong and muscular ventricle, which must be called hypertrophied, even taking into consideration the strength of the whole body.

In spite of having been laboriously and uninterruptedly occupied for more than six hours with the body of this unfortunateman, and that, too, with the assistance of my friends, I feel that many of my observations might have been more accurate. Yet the circumstances are such for each single observer, that it is only from the repeated observation of many that sure results can be obtained, to which the present paper may be a contribution.—*Abridged from Müller's Archiv, Jahrgang, 1838; Heft. V.*

[It is satisfactory to think that these skillful experimentalists failed so completely, and that Seb. Zink's earthly troubles were really over at thirty-six minutes and a half past nine. The instinctive belief that when the head was off, the man would die, was more cheering than the modern theory that the head may survive decapitation for some minutes. If this were true, it must be confessed that experiments like those detailed above would be very cruel. Some evidence in favour of this supposition will be found in Dr. Rigby's paper on the Pathology of Decapitation, which contains a number of cases from Nasse's memoir. It is to be found in our 18th volume, p. 21.—TRANS.]

### M. DONNÉ ON MILK.

THE following *résumé* is given by the author at the conclusion of his memoir "on Milk," &c.

1. The chemical history of the phenomena which milk presents when left to itself, can be completed only by microscopic observation.

2. Milk may be defined a liquid holding in solution, casein, as the blood contains fibrine, a peculiar sugar and salts; and holding in suspension globules of fatty matter or of butter.

3. The solubility of the milk globules in alcohol and ether, which do not dissolve casein, on the one hand, and on the other, the want of action of the aqueous solution of iodine, which does not colour the milk-globules, but does colour casein (as it does all azotised organised matters) yellow, prove that the casein does not form part of the globules, and that it does not exist in milk in a concrete state.

4. All the milk globules may be retained by the filter, and the filtrated liquid, transparent as water, will deposit casein under the influence of acids; this experiment also proves that the casein is in a state of solution, and moreover that the white colour of milk depends on the fatty matter suspended in the form of very fine globules; milk may therefore be regarded as an emulsion.

5. The first phenomenon which milk left to itself presents, is the ascent of the cream: cream is formed by the milk globules collecting at the upper part, in consequence of their specific gravity; below the cream is the milk properly so called, in which there are however two distinct layers; the upper one whiter than the lower, which is a little greenish, and semi-transparent. These differences of shade depend only on the greater or less quantity of milk globules

contained in the different layers of liquid, which are arranged according to their specific gravity. Cream exists, therefore, in the milk at the moment of its exit from the body, and milk and cream differ only in the proportion of fatty or butyraceous globules which each contains.

6. The second phenomenon observed is the change of milk to the acid state; it is in fact well demonstrated that this fluid, when it comes from the body, is alkaline; gradually the cream thickens, the casein coagulates, gases are disengaged, the smell of *Brie* cheese is perceived, and the microscope exhibits a number of infusory animalcules and vegetables; a real putrefaction in short, is established.

7. It is necessary to distinguish the part which the cream or non-azotised portion and the casein or azotised portion, each takes in this decomposition or fermentation. For this purpose the two elements must be separated by the filter, and it is then observed that the cream rapidly becomes very acid, while the serum, deprived of fatty matter and holding casein in solution, tends to the alkaline or putrid fermentation.

8. The infusory vegetables which are produced in this case do not appear till a long time after the milk has passed to the acid state; they cannot, therefore, be regarded as the cause of the fermentation, as the vegetables discovered by M. Cagniard Latour in the liquids undergoing the alcoholic fermentation, are; and as to the infusory animalcules, they exist as well in the alkaline as in the acid portion of the fermenting milk.

9. The microscopic vegetables of the milk, figured by M. Turpin as resulting from the transformation of the milk globules themselves, are equally developed on the surface of butter, previously melted and treated with ether, and on the surface of milk which has been filtered and entirely freed from globules.

10. No experiment can demonstrate the existence of one or of two vesicles in the milk globules: all the facts establish, on the contrary, that they are perfectly homogeneous.

11. The best method of preserving milk is boiling it on a sand-bath in vessels which are afterwards hermetically sealed.

12. The butter resulting from the agglomeration of the fat globules of the milk may be obtained in a vacuum of carbonic acid gas, in hydrogen, &c. It cannot, therefore, be admitted that it is formed under the influence of the air by a combination of oxygen or acidification.

13. There is a constant relation between the secretion of *colostrum* in women before

delivery, and the secretion of milk after. Women are, in this respect, divisible into three classes. 1st, Those in whom there is scarcely any secretion of milk to the end of gestation; and in whom there is secreted only a viscid liquid containing scarcely any milk globules, and but few granular bodies; in these the milk after birth is poor, and in small quantity. 2d, Those in whom the milk before birth is more or less abundant, but poor in milk globules, which are small, ill-formed, and often mixed with mucus-globules as well as granular bodies; these characters indicate a greater or less quantity of milk after birth, but that it will be poor and serous. 3d, Those in whom the *colostrum* is rich, in well formed and full sized milk globules, and mixed with no other substance than the granular bodies: these characters in general announce an abundant supply of rich and good milk after birth.

14. With respect to the influence of age on nurses, it is remarked that among the people of Paris, it is rare to find a good one after thirty, while those in the country are in their full vigour at that age; as to the influence of locality, it appears from the tables of mortality that the mortality of children is least in prosperous provinces, among people who have plenty of cattle, and especially of cows; in this respect Normandy holds the highest rank. The colour of the skin and hair does not appear to have the influence generally attributed to it; among 400 nurses the results were balanced between the brunettes and the blond; but among 9 red-haired women only 5 presented satisfactory qualities. The development of the superficial veins of the breast, and various sensations which women feel during gestation, are unimportant; while the development of the nipple, the brown or at least well-marked colour of the areola, and a certain firmness of the breasts, accord generally with an abundance of good milk. The external appearances which are most important in this respect, are a certain degree of general plumpness, and a moderate fulness of the breasts.—*Comptes Rendus*, Sept. 18, 1839.

## PROLAPSUS OF THE UTERUS.

DR. GRUNN, of Reppen, relates the case of a woman, æt. 28, who, when in the fourth month of pregnancy, in consequence of a violent effort, had a prolapsus of the uterus. Gestation nevertheless went on, without any accident, to full time. When Dr. G. saw her, thirty-six hours had elapsed since labour had set in, and twenty-four

since the waters had been discharged. The uterus hung between the patient's thighs; it was six inches long, and eight thick. The vertex of the child presented, and the neck of the uterus was dilated to the size of a two-franc piece. Not being able to obtain a greater dilatation, Dr. G. made an incision three inches in length in one side of the neck of the uterus, and a dead but well developed child was extracted. The delivery of the placenta was attended with very profuse hæmorrhage, which was arrested by injections of cold water. Afterwards the uterus was reduced and every thing went on well. The woman recovered, and notwithstanding the advice of Dr. G., refused to wear a pessary. — *American Journal of Med. Sciences.*

### COLLEGE OF PHYSICIANS.

The following gentlemen have been added to the list since last year:—

#### FELLOWS.

GEORGE GREGORY .. Weymouth Street.  
FREDERIC COBB..... St. Helen's Place.  
HENRY DAVIES..... Saville Row.  
G. MANN BURROWS.. Upper Gower Street.  
H. SUMNER DYER.. { Cambridge Terrace.  
                                    Regent's Park.  
HENRY JEAFFRESON Finsbury Place South.

#### LICENTIATES.

ROBERT SPEAR ..... Mitre Court, Temple.  
JOHN LEE ..... Grafton St., Fitzroy Sq.  
WM. FITZHERBERT .. Hanover St., Hanover Sq.  
JAS. THOS. HANSARD Southampton St. Bloomsb.  
WILLIAM ROXBURGH Gloucester Pl., Portm. Sq.  
PATRICK BLACK .... Bedford Square.  
WILLIAM ANDREWS... Golden Square.  
WM. HOLT YATES.... Aldersgate Street.  
PATRICK S. FRASER..

*To the Editor of the Medical Gazette.*

SIR,

THE recent regulations at the Royal College of Physicians in London having done away with the title of M.D., it is recommended to all gentlemen who belong to that College to have attached to their name the word *Physician*, in order to distinguish them from the unqualified person.

\* \* \* \*

Nov. 13, 1839.

### ST. THOMAS'S HOSPITAL.

DR. ROOTS resigned the office of Physician to St. Thomas's Hospital some weeks ago; we believe on account of his health, he having for some time suffered severely from rheumatism.

Dr. Lister, the Assistant-Physician to the hospital, has succeeded him, and

Dr. Barker has been elected Assistant-Physician in the place of Dr. Lister.

### UNIVERSITY OF EDINBURGH.

DR. JAMES HAMILTON has resigned the Chair of Midwifery. The worthy Doctor, though still often known by the cognomen of "Young Hamilton," is considerably above threescore years and ten; and is besides, we regret to learn, in a precarious state of health.

### LITERARY ANNOUNCEMENT.

Dr. Humble has in the press, a Geological and Mineralogical Dictionary, including the terms generally used in Botany, Conchology, Comparative Anatomy, Entomology, Zoology, and those other branches of Natural History connected with the study of Geology; in which the words will be deduced from their Originals, and their signification illustrated by quotations from the best authorities.

### LECTURES ON THE PRINCIPLES AND PRACTICE OF SURGERY.

*Delivered at the Westminster Hospital School,*

BY BENJAMIN PHILLIPS, F.R.S.  
Surgeon to the St. Marylebone Infirmary.

#### SUPPURATION.

*Definition—Different opinions; value of those opinions?—Gulliver's, Gendrin's, Donne's, Andral's—Is a pyogenic membrane necessary?—Suppuration rapidly excited—Symptoms—Pus; its characters, physical, microscopical, chemical.*

SUPPURATION is an operation of the living body, in virtue of which a *sui-generis* fluid termed *pus* is secreted. I use the term *secreted* advisedly, because I do not believe that pus, presenting all its essential characters, is formed in the circulating mass. I do not, however, deny that it may sometimes be absorbed, and carried into the circulation, though this is not proved; nor that it may be secreted and presented upon the inflamed surfaces of the blood-vessels, and be mixed with the blood.

It is interesting, while treating of a subject of such surpassing importance, to glance at the opinions which have been entertained with reference to the production of pus. The speculations of Hippocrates and Galen led them to refer the production of pus to the transformation of the blood; this was the earliest current doctrine, and it prevailed through the middle ages. Hippocrates (*De Morbis*, lib. i. sect. 12) says—"Quum venula convulsa rupta fuerit, sanguis effusus putrescit ac suppuratur; si verò caro convulsa fuerit aut contusa, sanguinem ex venis sibi ipsi propinquus trahit, atque hic putrescit ac

suppuratur." Galen (*in Aph. Hippocratis*, lib. ii. aphor. 47) says—"Pus ex sanguine ortum habet qui semi-malam (ut quispiam dixerit) habet transmutationem." Boerhaave and many of his followers attributed the formation of pus to a dissolution of the solids, and to the changes which supervene in extravasated blood; Pringle, Gaber, Benjamin Bell, to the putrefaction of serum; Quesnay and Dehaen to modification of *buff* or *coagulable lymph*. Dehaen (*De Generatione Puris; pars altera rationis medendi in nosocomio; tome ii. Vindobonæ, 1761*) says—"Communis sententia fert pus prægressâ simplicis inflammatione generari; inflammatione namque in abscessum verti, dum inflammatus sanguis in finibus vasorum stagnans et tamen à tergo pulsus, suorum vasorum extrema solvit, inque album cum iisdem vertitur pulvem; hanc obrem et inditurnâ puris excretionem oportere ingentem reperiri substantiæ consummationem," &c. Hoffman and Grassot to a melting down of adipose matter; Stewart to the putrefaction of chyle. In 1722, Dr. Simpson, of St. Andrew's, suggested that pus is formed in the capillary vessels by a process analogous to secretion. "If," says he, "any foreign body be introduced between the edges of a wound, and the external air excluded, pus will continue to be discharged as long as you please, so that by this means a kind of new gland is, as it were, produced. According to Thomson, towards 1756 Dehaen propagated a somewhat similar opinion. But the first treatise upon this point of doctrine which was submitted to profound discussion, was the Inaugural Dissertation of Dr. John Morgan, sustained in 1763, intitled "*Puopoesis, sive tentamen medicæ de puris confectione.*" All the principal circumstances of the function are here set forth with precision, and the author sustained with advantage against Dehaen, that inflammation is necessary to the formation

of pus. By Sebald—Justin—Brugmann (1785), the question was considered under all its aspects, and previous hypotheses were submitted to the proof of chemical experiment. Hunter, in developing this doctrine with that rare talent which distinguishes all his works, is regarded as the creator of it. By Chaussier, and particularly by Dupuytren, the subject was profoundly considered, and the opinions of Hunter confirmed. Later in life Dupuytren's ideas on the subject seem to have undergone considerable change. In the article *Abscès* (Dict. de Méd. et Chir. Pratiques), he states that pus is the result of *softening* of the *detritus* of altered tissues mixing itself with the blood which penetrates the part to constitute a pulpy matter, which is gradually converted into pus. These ideas, admitted only by a few persons, come with bad grace from a person who, more than any other, contributed to establish in France the previous doctrine. Gendrin made a connected series of microscopical observations, from which he deduced the following results:—That the globules of blood, altered by the stases which they experience in inflammation, even in the vessels, may be converted into globules of pus, or may escape from the capillaries in the state of pus; but then he stated also, that coagula may be converted into pus; that blood injected into the cellular tissue, and traversed by a seton, is rapidly converted into pus. Kaltenbrunner divides the act into *imperfect* and *perfect*. In the first we perceive small flakes detached from the stagnant points; others arising in the parenchyma itself. If the inflammation lasts long enough, suppuration becomes perfect, many flakes join together, and form grumous agglomerated masses, constituting the elements of pus, in the form of small very undefined corpuscles; they join, form canals, in which the corpuscles oscillate freely. A part of the parenchyma is consumed in keeping up the secretion of pns. Carswell, who accepted too implicitly the experiments of Gendrin, says—"From the very obvious characters of the facts elicited by microscopical observation, no doubt can be left in the mind that the formation of pus is a consequence of a modification of the blood, manifested more especially by a change taking place in the colour, transparency, and bulk of the globules of this fluid, after its circulation has been arrested in the capillaries by inflammation; that this change in the globules takes place in the capillary vessels." "Such is one mode in which pus is formed; that, in fact, which has been likened to the process of secretion. There is, however, another mode which, to a greater or less extent, is

perhaps always in operation at the same time with the former, but which, under certain circumstances, is effected alone, and from its not having been properly understood, has created much confusion, and given rise to opinions the most repugnant to the principles of a sound and philosophical pathology; I allude to the formation of pus in the blood under circumstances in which the influence of the capillary system, as exercising a function of secretion, can have no part." He alludes to the change of effused blood into pus; but he also says, he has observed it in the blood which has ceased to circulate in inflamed veins. Again, "that in phlebitis the conversion of the blood into pus can often be most satisfactorily demonstrated. As soon as inflammation of a vein has acquired a certain degree of severity, one of the most remarkable circumstances which attracts our notice is the cord-like hardness of the vessel. The blood has ceased to circulate through it; it has coagulated. At a subsequent period, however, we find that this state of the vessel becomes less conspicuous, and disappears sometimes suddenly, no cord-like swelling or induration being afterwards felt. Now further examination shews that the latter occurrence was the result of the blood having been converted into pus." Further, "from all these facts it must be evident that the capillaries could have no share in the purulent transformation of the blood." Mr. Gulliver says that the result of his examination of the blood of persons suffering from inflammatory fevers and hectic, has been the detection of pus in almost every instance in which there was either extensive suppuration, or great inflammatory swelling, without a visible deposition of pus in any of the textures of the body. "I have detected pus in the blood by examinations very simple, partly chemical, partly by the microscope. Water has a rapid and energetic action on the blood corpuscles; now the globules of pus undergo no change after being long kept in water. Accordingly, if the suspected blood be mixed with water, the blood corpuscles will soon become invisible, and any globules of pus that may be present will subside to the bottom of the vessel, and may be easily seen, and have their character determined, with a good microscope. Ammonia instantly renders the blood corpuscle invisible, while that of pus is acted upon but slowly by the alkali; and the different action of acetic acid on blood and pus is equally remarkable. He relates some instances of pus in the blood, independently of suppuration out of the vessels; this fact seems to be of some im-

portance, for it must be inferred that the pus was not absorbed, but formed in the blood.

We must now inquire whether the opinions to which I have alluded upon the formation of pus are or are not well founded. Are the cases referred to by Mr. Gulliver, of pus being found in the blood of patients dying from inflammatory affections, entitled to be ranked in science as admitted and well established facts? Of this I apprehend, for the following reasons, there is some doubt. If blood be examined while circulating in the transparent parts of certain animals, we see a fluid passing under the field of the microscope, holding in suspension globules of pretty uniform size; these are the blood-globules. *And while the blood is circulating in the human body, no other globules have, so far as I know, been demonstrated*; but if blood be removed from a person in perfect health, and placed under a microscope, a certain number of whitish pus-like globules may soon be observed. In examining frog's blood, Spallanzani discovered two kinds of globules, but the circumstance did not excite much attention. Recently, Wedemeyer made similar observations; but attention was principally directed to the subject by the experiment of Müller. He filtered frog's blood, which contains globules too large to pass through the filter—a circumstance which always happens with the blood of mammifera. When the filtered fluid was examined through the microscope, it was found to contain a large number of globules; these are the "lymph globules" of Spallanzani. The explanation of this phenomenon appears to be the following:—The serum of the blood, while circulating, holds a certain quantity of fibrin in solution; but when removed from the body the serum is no longer capable of maintaining the dissolution of the fibrin; it therefore coagulates, and assumes a more or less perfectly globular appearance. After death, if the blood be examined, these "fibrinous" globules will be found very numerous (Mandl). If blood be taken from the system, and immediately placed under the microscope, few of these globules will be seen; but if the observation be continued, they will appear to start up in all directions. In blood so examined, besides the blood and the "fibrin" globule, others may be observed, much smaller, probably globules of albumen precipitated by the salts of the serum; they are about 1/400th to 1/500th of a millimetre in diameter. If the serum of pus be heated, it will be found to yield similar globules. Probably these small molecules are the same that Sir E. Home referred to in human blood. It is at present uncertain whether they be

globules of chyle or of coagulated albumen. The other and larger globules, particularly pointed out in mammifera by Mandl, in a paper read at the Institute, Sept. 25, 1837, and by Magendie and Dr. Davy, are isolated, white, mammellated, as if composed of many smaller bodies. (See fig. 11, *a* and *b*, from Vogel, the former exhibiting them in their natural state, the latter after being acted upon by acetic acid.) Their diameter varies from 1/80th to 1/110th of a millimetre; they are always larger than the ordinary blood globule. These globules, chemically or microscopically examined, would seem to be coagulated fibrin; and Mandl proposed to name them "fibrin" globules. They are, like pus globules, insoluble in water, and they are altogether similar in size, colour, and chemical properties, to the pus globule (figs. 1 and 5, from Gueterbock and Henlé), and the mucus globule (fig. 4, from Gueterbock) to those of the saliva and those of the urine. These are, I apprehend, the globules which Gulliver and others conceived to be the pus globule, but which may be found in every specimen of healthy blood which has ceased to circulate, or which has been a short time removed from the body, and, so far as I know, only then. Whether or not this globule be in all respects identical with that of pus, of mucus, of saliva, and of urine, may admit of possible question; if it be, still the pus globule does not exist in the circulating blood. Even if it were found in the circulating blood, it does not imply that the fluid known as pus does not differ from these globules found in the blood. The essential characters of pus, mucus, saliva, and urine, do not depend upon these globules, which in each case appear similar to the white corpuscles found in the blood; else why do these fluids differ in their nature? The nature and specific character of pus do not clearly depend upon the globules. The globule of variolous matter does not differ from that of syphilis, but in its essence there must be a vast difference. That these globules do not constitute pus is evident upon another circumstance: see the deleterious effects which follow the introduction of even a small quantity of pus into the circulating system. I believe, therefore, that the statements of Mr. Gulliver and others, that the pus globules may be found in the blood in cases of inflammatory fever or suppuration, if they restrict its application to blood either stagnant or removed from the body, is correct; but incorrect as applied to the circulating mass: still I guard myself by assuming the identity of the pus globule with the fibrin globule. To my mind, a still further confirmation that the pus globule

does not exist in the blood, but is held dissolved in the serum, and not separated until it has passed out of the vessels, is the evidence of Bruggmann and others, who have observed that pus, at the moment of its secretion, is fluid and transparent; that after its secretion the fluid gives birth to globules, which rapidly increase. This is also the case with milk, mucus, and other secretions.

Is the evidence furnished by Gendrin, of experiments and observations made upon frogs, conclusive, as to the pus globule being a decorticated blood globule, entitled to confidence? I think not; and yet the statement he makes, that he has observed the progress of decortication, is so minute, so circumstantial, that it is difficult to conceive any source of error. He says he has seen the cortex at all periods in the progress of removal, in the vessels of a frog's web: here, on the threshold of inquiry, I feel this difficulty.

It is not clearly proved, that in all animal inflammation is capable of exciting suppurative action: in the higher genera of mammifera the action can be readily excited, but in the lower of them, much irritation may be applied without exciting this secretion; for instance, Gueterbock inserted setons into rabbits without seeing any traces of pus. In birds it can be rarely excited; and this fact, the discovery of which has been referred to comparatively recent observers, was evidently known to Macdonald. In the experiments he made upon the regeneration of bone, he employed many pigeons, and the fact to which we are alluding he speaks of in the following terms:—"Omnia hæc animalia paucis exceptis, convalescunt; neque in ullo, quod sane mirandum est, ullam suppurationis vestigium invenire potui." Hertwig made a similar observation. Gueterbock made, upon a pigeon, the following experiment, to assure himself whether Hertwig's opinion was correct:—He made an incision through the pectoral muscle, into which he inserted a pea; at the end of four days the wound was still dry, and the pea presented nothing on its surface. Another incision was made, and a ball of red precipitate inserted: at the end of two days the wound was scarcely moist, and the red precipitate was contained in a little sac, having undergone no change. Hertwig even went so far as to use the red-hot iron with no better success. With respect to reptiles, the evidence is unsatisfactory: Gendrin and Kaltenbrunner used frogs, for the purpose of demonstrating the modes in which pus may be found. Emmert never succeeded in exciting purulent secretion in those animals, whatever irritant he employed. Gulliver informed me that he has made a

very extensive series of experiments on frogs, for the purpose of exciting suppuration, but had never succeeded: he has observed, when there was loss of substance, that the reparation was effected by means of a "growing up," but no pus was secreted. He informed me further, that when he mentioned his experience on the subject to Müller, he wondered that he had never succeeded. This would imply that his belief was that it might happen. Gueterbock's experience is similar to that of Gulliver. Müller's experiments on eels had not succeeded in producing suppuration.

That M. Gendrin may be right in the opinion that white globules do become apparent when the blood has ceased to circulate, is probable, because the fibrin globule in the frog is a very prominent object; but that the blood globule, as seen under the microscope, has been observed to become despoiled of its colouring envelop, and to become immediately *twice as large as it was before it had parted with this envelop*, is what I confess my inability to admit. Accepting the fact of his having observed those white globules in stagnated blood, and believing him to have been unaware of the existence of any other than the blood globule, the explanation which he has given might naturally occur to his mind; and it is always dangerous to observe with a preoccupied mind. But if he mean that these white globules can be observed in blood whose course in the capillaries is *merely retarded* (tom. ii. p. 483), then I believe him to be in error.

That blood, having ceased to circulate, may be converted into pus, is maintained by Gendrin on the following evidence:—If we examine with the microscope a portion of cellular tissue, where the naked eye discovers a mixture of bloody serum and pus, we ascertain, first, that at a certain distance from the place where the pus exists, there is only a transparent fluid without globules; a little nearer, a certain number of globules exactly similar to those of the blood are found: as we approach nearer to the point, the globules are changed; by little and little they lose their transparency, and at the point itself they are found perfectly opaque. So, he would say, in this experiment we may establish, *first*, fibrinous globules in the midst of the serum; *second*, a gradual transformation of these fibrinous globules into purulent globules. Again, if we pass a seton through a portion of an artery which is obliterated by coagulated fibrin, this fibrin *suppurates*; it is *softened*, and *gradually converted into pus*. This same conversion is observed around grains of lead or mercury introduced into a portion of an artery previously emptied of the blood it contained. A coagulable matter oblite-

rates the vessel; it is *softened and converted into pus around the foreign body*. If we inject a solution of nitrate of silver, or caustic potash, into an artery or a vein, in which the circulation has been momentarily interrupted, and afterwards suffer the blood to return into the part, and retain it with a double ligature, we see the blood at first coagulated, afterwards discoloured, and progressively changed into pus. If, after having irritated in different ways the web or mesentery of a frog, we observe with the microscope the modifications which the blood undergoes in the irritated parts, we see the blood at certain points circulating more rapidly, but in other points it is gradually retarded; and at these latter points the eye may follow the changes which the blood globules experience—they wrinkle, disembarass themselves of their coloured covering, gradually lose their transparency, and arrive at the edges of the solution of continuity, or the point where the irritation is greatest, transformed into pus globules.

That you may impress upon the economy a disposition to suppurative action, is evident. The inoculation of small-pox is good evidence of this fact. That you may, in some very rare instances, find pus in a coagulum, I will admit. That in a small proportion of such cases, inflammatory action has not been detected, is also true; but surely no one would, on that account, deny that it has existed. It is also true that in the great majority of such cases inflammation has been detected; in fact, what an extremely small proportion of persons die without inflammatory action, and these clots are always found after death. I do not, however, admit that a tithe of the cases in which the phenomenon was observed were cases of pus in the clot at all, but simply a softening of the fibrine. In speaking of them, Dr. Carswell says, “the fluid matter of these concretions, so far as my observation goes, never resemble pure pus; it is a thin grumous grey or reddish-coloured fluid, of a puriform character.”

That blood injected into our tissues may excite inflammation, is unquestionable; that a coagulum may form in vessels under inflammation, is equally certain; that a seton may develop inflammatory action, when passed through a clot and the living tissues in its vicinity, no one will deny; that the inflammatory action so excited may be suppurative, if the inflammation be sufficiently intense, is clear; that a coagulum, whether in or out of a vessel, may soften and break down, mix with the pus resulting from inflammatory action, and so be ultimately completely discharged in the form of pus, I am ready to admit;

but I will exhibit the reasons which embolden me to deny that the coagulum breaks down into or is transformed into pus. Fortunately the experiments of Gulliver upon the softening of fibrin, throw much light upon this subject. “If (says he) a vein becomes obstructed with coagulated blood or fibrin, which cannot easily be absorbed or organized, in consequence of the very feeble vitality of the patient, the clot may be expected to soften; and it is, accordingly, in such cases that the clot is found softened at the centre. Again, he says, in repeating the experiments of Gendrin, in which a seton was passed through a clot of blood either in or out of the vessels, I could only twice succeed, after numerous trials, in producing any thing like pus in the substance of a coagulum. In these animals, which were greatly reduced from the effects of previous operations, the matter proved to be nothing more than softened fibrin.” Again, “when two ligatures were so placed on a vein as to include an inch or two of the column of blood, it took about three hours to coagulate perfectly. In two or three dogs, it lost its colouring matter, becoming whitish, tolerably firm, and shrunken. After a seton or a leaden shot was put into the clot, no appearance of a purulent-like fluid was seen towards the centre, although pus was frequently present between the coagulum and lining membrane of the vessel, and still more often in the cellular coat and neighbouring parts.”

The conclusions he draws from numerous observations which he has detailed, are—“that coagulated fibrin, when removed from the body and subjected to a blood heat, begins to soften in about forty hours, assuming the colour and consistency of pus, but easily distinguishable from it by microscopic and chemical examination; that the purulent-like fluid found in the fibrinous clots of the heart and arteries, and so frequently in the veins, is essentially distinct from pus, and analogous to, if not identical with, softened fibrin; that the softening of coagulated fibrin is an elementary pathological condition of frequent occurrence, distinct from suppuration, and constituting a considerable proportion of the cases generally denominated suppurative phlebitis; that I have observed pus mixed in considerable quantity with the pulpy fibrinous matter, and, in two instances, some purulent globules were observed, completely insulated in the centre of a clot from the neighbouring tissues: but in both these cases pus was also detected in the blood; and when it is considered how frequently this contamination exists, it will not appear surprising that the particles of

pus should be found entangled in coagula contained in these vessels?"

If Donné's experiments be correct, there might be less difficulty in admitting the probability of this occurrence. He says, if we mix together one part of laudable pus and nine parts of blood, at the moment it is taken from the vein, a clot is formed; but at the end of six, twelve, or twenty-four hours, this clot is liquefied, and if the proportion of pus to the blood be less considerable, the liquefaction occurs sooner. If at the end of six hours it be submitted to the microscope, we see already blood globules which have lost their colour and their regularity, and the next day, in their place, nothing but pus globules are seen. Upon this experiment he rests the following reasoning:—"Pus arises from the blood, and is only a modification of it." By this he explains the rapidity of suppuration and the vast collections of pus which are formed in certain affections. If this experiment be good, of which there is considerable doubt, it would imply that those collections of "pus" in coagula, to which reference has been made, could not be pus; otherwise, how happens it that the clot has not been broken down? They must have come together under the most favourable circumstances for this action; and that they must have existed for more than twenty-four hours, must be evident from the fact that most of the colouring matter has been removed.

With respect to the experiment of injecting blood into the cellular tissue, or the breaking down of a clot in a vein, so much is certain, that inflammatory action is always excited at the part—that pus may be exhaled as a consequence of that action—that the fibrinous matter of the blood, subjected to the heat of the body, after having ceased to circulate, will rapidly soften—that it would mix with the purulent matter secreted around—and that the fluid ejected would have a purulent aspect; but then it is pus largely mixed with softened fibrin.

Andral says, there are cases where during life no symptom of irritation has revealed, that pus is found at a point where we find it after death, and where any actual or antecedent trace of inflammation could not be detected; colour, consistence, every thing, being normal where the molecules of pus are found. It occurs frequently that it is not only at one point that this accumulation of pus, without any appreciable lesion is found, but often at many at the same time. In the cellular and intermuscular tissues, the liver, the spleen, and the lungs, at the same time: each of these organs may contain a single point or

be studded with them. If in this case we examine the interior of the vessels, sometimes pus is found mixed with the blood, sometimes no trace of it can be discovered in them. In these same cases, sometimes, no trace of suppuration can be detected elsewhere; sometimes, however, purulent collections in many points, at the same time, are detected after great operations. The question for consideration, is, are these purulent collections the result of absorption? It may be so, when they are found in cases, where not long before death, a considerable purulent collection existed in some part of the economy. As to those cases where similar purulent collections are found without previous evident suppuration—in cases where, for instance, pus is found in a coagulum—we have already disposed of that question.

I believe that no suppuration can happen without inflammatory action. In treating of inflammation, I shewed that inflammation was accompanied by the secretion and exhalation of certain fluids. I believe those secretions, *unless there be rupture of vessels*, are always the serous portion of the blood: once effused the fluid will separate into two parts, a globular portion, and a more fluid portion. The denser part may take the form of lymph, or false membrane or pus; it is in either case globular, and the globules are similar; the impression of the peculiar character of lymph, false membrane, or pus, upon the fluid, is, I apprehend, what may be termed a vital act, depending upon the peculiar nature of the inflammatory action; the effused fluid holding in solution the substance which afterwards constitutes these globules being a constituent part of the blood. Passing through certain parts or tissues of the body, this constituent material of the blood undergoes various modifications: in the one case it is presented as mucus, in another as pus, in another as saliva; in one, the pus of small-pox, in another that of syphilis, in all the globule being uniform. Inflammatory action then excites the effusion of a fluid differing from mucus, saliva, and urine, but possessing certain peculiar characters. Whether or not, in all cases, the presence of an exhaled layer of lymph be necessary for the percolation of this fluid, it is difficult to say; that lymph is usually exhaled before pus, is true; whether that lymph be arranged in the form of a membrane, such as is found in the interior of abscesses, or on the surface of suppurating wounds, is not equally manifest; that the vessels themselves undergo a change of structure in some cases of inflammatory action is clearly shewn: it is certain that the internal tunics of arteries may become spongy, thickened; that the

membrane of veins may present a tomentous or villous aspect; but whether or not these or any similar changes in the vascular system be necessary for a purulent formation, is what in the present state of our knowledge cannot be determined. The "new gland" of Dr. Simpson was no doubt the pyogenic membrane of Hunter, Dupuytren, Beclard, and Delpech; this membrane is seen in the interior of abscesses, upon the surface of suppurating wounds, and in fistulous canals. It is said that it is formed by the granulations which themselves result from the development of the celluloso-vascular system of the part, by inflammatory action. Through this membrane the secretion of pus is supposed to take place, and the secretion like all others is effected by the action of certain powerful medicinal substances, change of temperature, mental excitement; in fact, by all mechanical, chemical, and vital agents. There can, however, be no question that although this accidental membrane can usually be demonstrated when a purulent secretion has existed for some time, that it may be also furnished by mucous, serous, fibrous, and cellular tissues. A bougie introduced into the urethra determines this secretion in a few hours. But for those membranes to secrete pus, their organization and their vital powers must be previously modified. Mucous membranes have little change to undergo, because their structure is very similar to the pyogenic tissue, and their secretion not very dissimilar; but the serous, the fibrous, and the cellular tissues, are necessarily considerably modified. It has been maintained by men of great ability, that the secretion of pus could not proceed without the development of this membrane. This is probably a too exclusive opinion; the probability seems to be in favour of the opinion that the secretion of pus precedes the appearance of this membrane, and in many cases where pus is found the existence of this membrane has not been demonstrated.

Upon the evidence I have now laid before you, I rest my opinion that Hunter is borne out in the statement that no suppuration can take place without inflammation: he says, "I shall endeavour to establish as an invaluable fact, that no suppuration takes place which is not preceded by inflammation; that is, no pus is formed but in consequence of it." Such was also the opinion of Beclard.

Suppuration can be very quickly excited by producing inflammatory action. Thus, John Hunter laid open the tunica vaginalis of a young ram, and exposed the testicle. The surface of the testicle was wiped clean, and a piece of tale was laid

upon it. The surface almost immediately became more vascular: five minutes after the tale was removed, and examined in a microscope, but no globules could be observed, only a moisture, which appeared to be the serum. Ten minutes afterwards there were irregular masses formed on the tale, some transparent, with determined edges, but no globules; fifteen minutes afterwards nearly the same. At twenty minutes after, there was an appearance of globules. At twenty-five minutes there were globules in clusters; but I could not say exactly what those globules were. At thirty-five minutes the globules more distinct, more diffuse, and numerous, and so on. Many other similar experiments were made with similar results. For instance, a canula was introduced into "the fleshy part of an ass's thigh at nine in the morning: at seven next morning it was removed and found to contain common pus. From these experiments, he says it would appear that pus was formed coeval with its secretion; but from Mr. Home's experiments it would rather appear that the globules were not formed till some time after secretion, and this sooner or later according to circumstances which we probably do not know. In eight hours after, a blister was applied. The fluid discharged was fully transparent, in nine hours it was less transparent, but free from the appearance of globules; in ten hours the discharge contained globules, which were very small, and few in number; in eleven hours more numerous, but still the fluid did not coagulate in sal ammoniac; in twenty-four hours the fluid was coagulated by sal ammoniac. Upon mucous surfaces "a bougie has excited it in five hours."

The act of suppuration excites in the economy a particular series of symptoms. Many of these are common to inflammation, others are peculiar to itself. John Hunter says, "the sensations arising from a disease generally convey some idea of its nature; the suppurative inflammation gives us as much as possible the idea of simple pain: without having a relation to any other mode of sensation we cannot annex an epithet to it, but it will vary in some degree according to the nature of the parts going into suppuration. The pain of inflammation is increased at the time of the dilating of the arteries, which gives the sensation called throbbing, in which every one can count his own pulse from paying attention merely to the inflamed part; and perhaps this last symptom is one of the best characteristics of this species of inflammation. As it proceeds towards suppuration, the pain is considerably increased; but when suppuration has actually taken place, the pain in some degree

diminishes, and the temperature of the part is lessened." There is a certain period in the inflammation when the suppurative disposition takes place, which is discovered by new symptoms taking place in the constitution, viz. shivering. Rigors from local irritation, attended with the full action and at regular stated times, have all the characters of an intermittent fever, but it may be observed in common: rigors preceding suppuration are not fol-

lowed by so much heat and sweating as intermittent is. It is an evidence of the constitution sympathizing—of fever being developed. "Some persons," says Hunter, "have supposed that fever was necessary for the operation of suppuration, and therefore that it did not arise from the sympathy of the constitution with a local injury, but as a necessary effect to become a cause of suppuration."

#### Pus.

Having considered how the fluid called pus is formed, we shall now proceed to examine it *physically, microscopically, chemically, and diagnostically*. Pus is a yellowish fluid, variable in smell and consistency; sometimes viscous, glutinous; sometimes fluid, sometimes without odour, sometimes fetid. The apparent variety in its character induced Pearson to establish four varieties, *creamy pus, curdy pus, serous pus, slimy pus*. When very fluid and very fetid it is termed *ichor*. Secreted on the surface of a healthy ulcer, or a moderately acute abscess, it is called *laudable* or healthy pus. It is then moderately fluid and viscous; when warm has a mawkish smell, which is dissipated by cooling and a sweetish taste. Gueterbock found its specific gravity to be 1.030; Pearson, 1.031 to 1.033, this slight difference depending probably upon the variety. It is, therefore, heavier than the serum of the blood, and lighter than the blood itself, the former having a specific gravity of 1.027 to 1.029, the latter 1.0527 to 1.057. According to Hunter, pus presenting these characters resists putrefaction energetically. This quality is re-

marked by Donnè—by Gueterbock, who says that, in his experiments, pus kept in a closed vessel was perfectly sweet at the end of six days. Gulliver informed me that he has had healthy pus in a window to which the sun had access for six weeks without becoming fetid; and, if carefully washed of all impurities, it will continue sweet for an almost indefinite time. Gueterbock says, that when he has tested healthy pus upon an ulcer, it has yielded an alkaline reaction, and what is singular, that taken from carcinomatous ulcers, wounds connected with necrosis, hospital gangrene, scrofulous ulcers, and syphilitic bubos, presented a like character. Very soon, however, it becomes neuter, and even acid. Such are the ordinary characters of pus. Examined through the microscope, we find pus composed of two parts, one fluid, and a substance floating, but insoluble in the fluid. No filter is capable of completely separating one from the other. Gueterbock says, he has always seen the filtered product—pus mixed with water, present a marked tendency to putrefy. If we examine the portion held in suspension, we find it composed of bodies

of *unequal* volume. Essentially different, therefore, from the blood globule. Thomson believes that Senae first spoke of these globules; but I apprehend the person who first pointed out those of pus and mucus was Gorn, in 1718. Afterwards Hunter demonstrated them, and described them with more care. With the exception of Kaltenbrunner, all authors, until very recently, spoke of only one kind of globule floating in pus; he describes in the blood of frogs, corpuscles and granules, but he says he never met with any other than granules of equal volume in human blood, and protected from atmospheric contact. Gueterbock has always seen globules of different sizes, the larger of which has been described by authors, and though they are more numerous it is certain that the smaller float among them. Gulliver has equally established the existence of the two bodies, the one of which he proposes to call the pus globule, the other the pus molecule; he believes that the molecule is the essential element of the globule, and that the latter may be reduced to the former condition by destroying the involucra by which it is invested. He says, "the pus globule is composed of central molecules, generally three in number, connected together by an external part, which gives shape and size to the whole; that the molecules are dense, smooth, and spherical, measuring from 1-10666th to 1-80000th of an inch in diameter; and that they differ from fibrin, and from any part of the human blood corpuscle, in their form, density, indispotion to putrefaction, and complete insolubility in acetic acid; that they are probably of a peculiar nature, and essential to the nature of pus globule. That the external portion which surrounds the molecules, so as to complete the pus globule, is analogous to coagulated lymph or fibrin, being rendered translucent or dissolved by sulphuric, sulphurous, oxalic, or acetic acids and the solution in the latter affording a precipitate with ferro-cyanate of potash. The medium diameter of the entire pus globule appeared in the author's millimetre to be something between 1-3000 and 1-2500th of an inch, although he observed that there are so many globules of both larger and smaller size than here indicated, that probably no measurement of the pus globule has ever been given which might not be verified by some one of corresponding magnitude. The consistency of pus depends upon the relative proportion of these two parts; if the fluid preponderates, it is thin; if the globules, it is more laudable. The globules are almost round; they differ slightly in form and volume, some being well rounded; a few being irregular, angular, rugous—like mulberries;

presenting such an appearance as might be expected from the super-position of the granules or molecules, upon other, and larger ones. The pus globule is always more transparent, paler, and commonly twice as large as those of the blood; Gueterbock found their diameter 0-0004 to 0-0005 of a millimetre, some larger. Gulliver, 1-2500th to 1-3000th of an inch; whilst, according to Weber, those of the blood do not exceed 0-0002. The granules are very much smaller than the globules, usually very inferior to that of the blood globule. Gulliver estimates them from 1-8000th to 1-12,000th of an inch. Gueterbock believed that the pus globule always presents the same form, whether examined in distilled water, sugar and water, albumen, or in the fluid part of pus; but if it remains long in distilled water or in alcohol, it undergoes certain changes; the edges become more transparent, the centre more opaque. Acetic acid dissolves the periphery, leaving the granules or molecules untouched; the involucra are dissolved; the granule resists. When the shell or envelope is dissolved by acetic acid, the granules become very apparent; their diameter does not exceed 0-0001 (Gueterbock), and they hang two or three together, as is shewn in fig. 3. Henle, maintaining his opinion that the fibrin globule is originally a portion of epithelium, such as is shewn at fig. 10, believes that the central nucleus is at first single, as seen at fig. 6; that it afterwards undergoes the successive changes shewn in figs. 7, 8, 9, ultimately acquiring a bilobed or trilobed character, and presenting such appearances as are presented at fig. 5. Gueterbock examined pus taken from a horse, through the microscope, but the globules did not appear similar to those of man. Mandl's observations are similar, but with this difference; he considers the globules mammeloned, two or three very small globules adhering together; but the form is usually spherical; some are lenticular. They do not easily lose their form; he has preserved them for many months with very little change; he believes that the central nuclei pre-exist. In his ideas of the size of the pus globule, he first refers to the admeasurements of Young, 1-3700th of the English inch; Weber, from 1-1500th to 1-3000th of the Paris inch. The greater number, according to Weber, have a diameter of 1-2400th of the Paris inch. Donn   believes the diameter to be seldom less than 1-100th of a millimetre, and usually more. Mandl has found them varying between 1-80th, 1-100th, and 1-110th of a millimetre in diameter. In the midst of this variety, the only conclusion to which we

can come is, that there is much diversity in the size of these globules. We can hardly believe that men so practised in microscopical observation as several of those to whom we have alluded are, can have come to such different conclusions with regard to an object which, we are manifestly assured, whether observed in mammifera or reptiles, is always of uniform size.

In making a *chemical* examination of pus, it has been thought desirable to effect the separation of the more solid from the more fluid part—the globules and granules from the fluid in which they float; but this has not hitherto been found practicable, for however fine the filter employed, the filtered fluid will be found turbid, and containing globules. If a small quantity of pus be carefully washed, so as to isolate the globules from the rest of the fluid, although we shall not often succeed, because pus makes with water an emulsion, and because a portion of the globules pass through the filter, yet in a small number of cases the globules will be fairly precipitated, and the fluid will remain perfectly clear. If we take those globules, well and carefully wash them, pour upon them concentrated acetic acid, and then filter, the envelopes of the globules will be found dissolved in the filter; add ferrocyanate of potash, and a sediment will be formed. What remained neutralized by carbonate of potash was at first turbid; then it precipitated; from whence Gueterbock concluded that the shell or involucre should be ranged among those substances which Berzelius calls albuminous, and which are precipitated by the ferrocyanate of potash. Acids do not dissolve the molecules which constitute the nuclei of globules. Whether, like the nuclei of the corpuscles of the blood, they are soluble in caustic potash, is undecided; probably they are; in fact this fluid, or a concentrated solution of carbonate of potash, renders the globules of pus more transparent, and less easy to distinguish. At the end of a little time some disappear, and here and there the debris of their envelopes, as well as their granules, are distinguished. If filtered pus be heated, flakes appear; alcohol, hydrochloric, and nitric acid, bring about similar coagulation—evidence of the existence of albumen; but the proportion is less than in the serum of the blood. The albumen of pus is not, however, more than that of serum, precipitated by sulphuric æther. This reagent, which Gmelin first employed, and which Müller approved of, suffices, therefore, to distinguish it from white of egg. A precipitate from the remaining fluid may still be obtained by

heat; consequently the albumen can have experienced no change.

It would be tedious to pass in review the various means and modes which have been employed in the analysis of pus. Gueterbock has found in 100 parts of pus, water, 86·1; fatty matter, soluble only in boiling alcohol, 1·6; fatty matter and osmazome, soluble in cold alcohol, 4·3; albumen, pyine, globules, and granules of pus, insoluble in alcohol either hot or cold, 7·4; saline matter, 0·8, of which seven parts were soluble in water, namely, much hydrochlorate of soda, and very little phosphate, sulphate, and carbonate of the same substance, hydrochlorate of potash, and hydrochlorate of lime; soluble in nitric acid, one part, namely, phosphate of lime, phosphate of magnesia, carbonate of lime, and some traces of iron.

Presuming these investigations to be correct, there are certain circumstances common to pus and blood; but iron enters more largely into the composition of the blood than into that of pus. Pus, however, yields a substance which is not found in the blood—*pyine*. If this be admitted, it must be evident that pus globules are not the essential elements of pus.

## LECTURES

ON

### THE PHYSIOLOGY OF THE STOMACH,

*Being the Gulstonian Lectures for 1839; delivered at the Royal College of Physicians in London,*

By R. B. TODD, M.D. F.R.S.

Fellow and Censor of the College; and Professor of Physiology, and of General and Morbid Anatomy, in King's College, London.

## LECTURE II.

THE stomachs of the large and interesting order of Ruminantia are placed at the opposite extremity of the scale from those of Man and the Carnivora; while the latter exhibit the minimum of development of the stomach, in its anatomical sense, the former have reached the maximum. The complication here, as I have already remarked, is clearly due to the subdivision of the cardiac portion. The fourth, or last stomach of the ox or sheep, is the analogue, both in shape and structure, of the simple carnivorous stomach. The cardiac portion is subdivided into three compartments, which, with the pyloric portion, make the four cavities, of which the ruminant stomach evidently consists. These cavities, it is important to notice,

communicate not only with each other, but three of them communicate with the œsophagus, so that aliment may be made to pass directly from the œsophagus into the first, second, or third stomach, according to circumstances. A striking contrast is thus afforded with the stomach of the porpoise: to reach the fourth cavity of the latter, the food from the œsophagus must pass through the first, second, and third stomachs, whereas in the ruminant

it need only enter the third (which it can do without passing into either the first or second), in order to make its way into the fourth stomach.

The varieties in form and structure of the separate cavities of the ruminant stomach afford interesting matter of observation. The largest cavity, usually called the first stomach, or paunch (*rumen*) *b*, fig. 2, constitutes the left or splenic end of the viscus. One or more irregular con-

FIG. 2.

The figure is taken from Carus and Otto's *Erläuterungstafeln*; it represents the sheep's stomach.

strictions are manifest upon its exterior, one of which, in particular, separates the œsophageal portion from the remainder and extreme left of the compartment. Several folds, or imperfect septa, project into the cavity. The mucous membrane of the paunch is everywhere covered by a thick, dense, and opaque epithelium. A multitude of lamellar processes, or papillæ, cover it over, composed of small folds of the mucous membrane, covered by thick epithelium. These processes vary considerably in shape and size in the different genera of the Ruminant order, as well as in different parts of the paunch. They

are entirely absent from the mucous membrane covering the fold which separates the right from the left portion of the paunch.

The second stomach, or *reticulum* (*honey-comb stomach*; *bonnet*, of the French), *g*, fig. 2, situate on the right and in front of the first, is much smaller than it, and differs from it materially likewise in the arrangement of its mucous membrane. It communicates freely with the œsophagus, through the same orifice as the paunch; and it likewise has a large opening of communication with this latter cavity. Its mucous membrane is characterized by

a number of cells developed upon its surface, polygonal in form, inclosed by distinct and prominent walls, the margins of which are serrated. The cellular arrangement is not distinct near the paunch; here the anatomical characters of the membrane exhibit a state of transition, from the folds or papillæ of the first stomach to the inclosed cells of the second.

The third stomach (plicated cavity, *palterium*; *feuille*, of the French) is the smallest of the four cavities, and is found to the right of the second. It communicates with the œsophagus through a groove or imperfect canal, which passes through the second stomach, and which, in fact, may be regarded as a prolongation of the œsophagus to the third stomach. This groove is formed by two strong and muscular bands passing downwards to the right side and in front of the orifice by which the second stomach communicates with the paunch. The groove is open towards the second stomach; but by the contraction of the muscular bands which form its walls, it may be closed in that direction, and thus converted into a true canal, so that fluids or other alimentary substances of small size may readily find their way through it, from the œsophagus to the third stomach. The mucous membrane of this stomach is arranged in longitudinal folds, which, as in the first and second cavities, are covered with a thick epithelium; numerous small triangular papillæ likewise are found on its surface, not unlike those of the second stomach.

The fourth stomach, *k*, fig. 2, (*abomasum*; *caillette* of the French) communicates by a large orifice with the third, and through the groove with the œsophagus. It constitutes the pyloric portion of the stomach, and is easily distinguished from the others not only by its situation to the right of the other compartments, but likewise, and more particularly, by its elongated shape, tapering to the pylorus. In shape, indeed, it is not unlike the simple carnivorous stomach; nor is this its only point of resemblance to that form of stomach, for its mucous membrane is smooth, soft, and destitute of an epithelium visible to the naked eye.

In the camels, llamas, and dromedaries, the paunch has lost its papillæ; its mucous membrane is therefore smooth on its internal surface; but in two situations numerous large and deep cells are found collected together, each cell, according to Meckel, having a depth of two or three inches, with an equal breadth. The second stomach in those animals is wholly occupied by cells, more numerous but less capacious than those in the paunch. The third stomach is remarkable for its great

size, whilst, on the other hand, the narrow dimensions of the fourth cavity are in contrast with its usual size in other ruminants.

In the first and second stomachs of ruminants, but particularly in the paunch, the food undergoes maceration; and probably through the peristaltic action of the muscular wall of the cavity a more complete admixture of it takes place. The food first received into these cavities has been imperfectly or not at all masticated; it is therefore returned, morsel by morsel, from the paunch to the second stomach, and from this latter to the mouth, where it is subjected to further mastication. It would seem the more reasonable doctrine to believe that the food for rumination comes directly from the second stomach, and not from the first, as some suppose. The paunch is too large, and in general too full of food, to allow of its contracting in such a way as to separate small portions in succession from the mass of its contents. On the other hand, the opening of communication between the paunch and second stomach is so free and so dependent, that the contents of the former can readily pass into the latter; and, moreover, from its small size, and its strong muscular coat, the second stomach is well adapted for pushing the food upwards into the œsophagus.

The experiments of Flourens, as well as those of Haubner, have thrown some light on the office of each compartment of the ruminant stomach. When sheep were made to swallow solid food in quantity, as lucerne, carrots, &c., and the animal was opened shortly after, the food was found principally in the paunch, but partly also in the reticulum; and if openings were made in the abdominal parietes, so as to form an artificial anus corresponding to each stomach, the food first swallowed came out at the orifices opposite the first and second stomachs. Food much masticated, and of small bulk, whether before or after rumination, was found to pass into the third stomach in greatest part, although a small portion found its way into the first and second; and liquids passed equally into all the stomachs. It would appear, then, that in order that the food shall pass readily into the first and second stomachs, it must be sufficiently large to dilate the lower part of the œsophagus, when it finds a ready passage into the first and second stomachs. The ruminated food, on the other hand, being so small in bulk, and almost semifluid, cannot dilate the œsophagus, but passes freely into the third stomach, along the groove which leads into that cavity, and thence into the fourth.

We next proceed to examine the anatomi-

mical peculiarities in the stomach of Birds.

In some birds there are one or more recipient and macerating cavities, which are merely offsets from or dilatations of the œsophagus, and in which, as in the paunch of the ruminants, the food must remain for a short time before it is introduced into the digesting stomach. These receptacles belong to birds of prey, which swallow large quantities of animal food at a time, and feed at long intervals; or, in a more developed form, to granivorous birds, whose food is of such a nature that it must be taken in large quantity to afford sufficient nutriment. The cavity in question is denominated the *crop*, or *ingluvies*. In the birds of prey, as eagles and vultures, it consists merely in a dilatation of the œsophagus on one side. In the granivorous birds, however, where, as Mr. Owen has remarked, the cavity of the gizzard is very much diminished by the enormous thickness of its muscular coat, the crop is more developed, and takes a more important share in the digestive process.

The common fowl and the pigeon afford favourable examples of the development of the crop. In the former, it is merely a single cavity, and the structure of its coats is essentially the same as that of the coats of the œsophagus (fig. 3), several follicles

FIG. 3.

are developed from its mucous coat. The pigeon, however, has two cavities of this kind, one on each side of the œsophagus (b, c, fig. 4). The cavity marked c, exhibits the altered state of the membrane, consequent on the secreting function which it takes on while the bird is rearing its young. The change which the food undergoes in the crop, observes Mr. Owen, is well known to bird-fanciers. If a pigeon be allowed to swallow a great quantity of peas, it will swell to such an extent as

FIG. 4.

almost to suffocate it. The time during which the food remains in the crop depends upon its nature; in a common fowl animal food will be detained about eight hours, while half the quantity of vegetable substances will remain from sixteen to twenty hours, which is one among many proofs of the greater facility with which animal substances are digested. Mr. Hunter made many interesting observations on the crop of pigeons, which takes on a secreting function during the breeding season, for the purpose of supplying the young pigeons in the calow state with a diet suitable to their tender condition. An abundant secretion, of a milky fluid, of an ash-grey colour, which coagulates with acids and forms curd, is poured out into the crop, and is mixed with the macerating grains. This phenomenon is the nearest approach, in the class of Birds, to the great characteristic function, the presence of whose special apparatus, the mammæ, has afforded the universally recognized title of the higher division of warm-blooded vertebrata; and the analogy of the "pigeon's milk" to the lacteal secretion of the mammalia, has not escaped popular notice\*.

The true stomach of birds is complicated by the addition of a powerful muscular apparatus to its pyloric portion, or rather to an offset from its pyloric portion. This muscle, commonly known under the name of gizzard, is destined to supply the place

\* Owen, in *Cyclopedia of Anat. and Physiol.* art. *Aves*.

of the usual masticatory organs of the mouth, and the greatest part of the food must be subjected to the action of the thick fleshy bellies of which the muscle is composed before it reaches the pylorus. The membrane lining the gizzard is covered by a thick and horny cuticle, which sufficiently protects the surface from the friction necessary to the perfect trituration or mastication of the food within it, aided, as it commonly is, by small stones or gravel, which the bird instinctively swallows to facilitate this process. Between the gizzard and the œsophagus, or the crop, when present, the true physiological stomach is situate, not very correctly designated by anatomists *proventriculus*; sometimes also called *bulbus glandulosus*. This cavity corresponds to the cardiac portion of the stomach; in some instances it does not exceed the width of the œsophagus, but in most birds it is distinguished as a dilated portion of that tube; it is, always, however, characterized by a series of follicles opening on the free surface of its mucous membrane. This surface is moist and smooth, and presents no appearance of epithelium visible to the naked eye. When the *proventriculus* is laid open, the orifices of the follicles are very apparent, varying in size, number, and arrangement, in different genera. In some they are simple follicles, of the same diameter at their blind extremities as at their orifices; whilst in others they are more complex, being wider at their blind extremities than at their orifices, and having a greater or less number of offsets from them, which themselves are but smaller follicles. In the purely carnivorous birds, the follicles are straight and simple; in the granivorous they are larger, more complex, and more numerous. This diversity of form is well seen in fig. 5, taken from Sir E. Home's Comparative Anatomy. The *proventriculus*, then, must be considered as analogous to the physiological stomach of mammalia; its mucous membrane is smooth, devoid of a thick epithelium, and it is the seat of an abundant secretion, which, as is now generally admitted, is identical with the gastric fluid of the mammiferous stomach. Another distinction between the stomachs of granivorous and zoophagous birds, it may not be uninteresting to mention, is to be found in the degree of development of the gizzard. In the latter, this organ is not so perfectly developed as in the former, for less mastication is required for the digestion of animal food in birds as well as in mammals, than for that of vegetable food: and it is curious to observe, that when a naturally zoophagous bird has been fed for a short time on grain, its gizzard acquires a very considerable increase of size, owing to the increased

muscular exertion employed to masticate the grain. This fact was first ascertained by Mr. Hunter, in the case of the sea-gull.

We see, then, that in the class of birds, as well as in mammalia, however complicated the anatomical stomach may be, there is one portion distinguishable from the rest by the absence of manifest epithelium and by a secreting surface, by which those actions are performed which physiologically distinguish the stomach from all other parts of the alimentary canal.

In reptiles and fishes, the stomach is in general of the simple form: a greater or less dilatation of the lower end of the œsophagus, with more or less extent of secreting surface. In the ophidian reptiles, so little difference is there in point of either size or direction between the œsophagus and stomach, that it is impossible to distinguish those portions of the alimentary canal by the ordinary anatomical characters: both are remarkable for their great dilatability. In the frogs, salamanders, and the testudinate reptiles, the stomach is manifestly dilated, and its internal membrane thrown into longitudinal folds; and in some of the latter order the

muscular coat is considerably developed—as the turtle. The stomach of the crocodile is remarkable for its similarity to that of birds, in the development of the muscular coat at the pyloric portion into a distinct digastric gizzard. There are not, however, the gastric follicles which characterize the proventriculus of birds; doubtless the seething apparatus is arranged here as in the simpler forms of stomach; but as I have not had any opportunity of examining the crocodile stomach, I cannot form any correct opinion on the subject. The chief variety in the stomachs of fishes is as regards its external form; in some there is no dilatation by which the stomach may be distinguished externally from the œsophagus; in others the stomach is oval or globular in form; in others, again, it resembles a retort in shape, with a more or less lengthened cardiac portion, and a rounded pyloric portion. The pyloric fold is in general distinct, and the whole lining membrane of the stomach is smooth, moist, and highly vascular; distinguishable from that of the œsophagus by the absence of the regular longitudinal folds into which the inner membrane of that canal is thrown, which extend quite into the cavity of the stomach.

I have thus given a brief sketch of the anatomical characters of the stomach in the four classes of vertebrated animals. Were I to extend the description to the invertebrated classes, which the limited time allotted to these lectures would not permit me to do, we should find, that in every instance, however numerous the compartments, or however varied the form of the stomach, there is always one portion, of variable extent, which corresponds to the description I have given of a true digesting or physiological stomach.

### ON SYPHILIS.

By HERBERT MAYO, F.R.S.

Senior Surgeon to Middlesex Hospital.

[Continued from page 277.]

[For the London Medical Gazette.]

*Accidents of primary syphilis—Phimosis—Bubo.—Constitutional lues; its nature and laws—Principles of treatment—Curative agents: mercury; iodide of potassium; sarsaparilla, &c.—Siphilitic affections of the skin grouped under two heads, the non-ulcerative and ulcerative—Appearances of some of the former; roseola, mottling, psoriasis.*

AMONG the accidents of primary syphilis may be included differences in the degree of pain and attendant inflammation.

In virulent phagedæna the pain is extremely severe; in the milder forms, the sore, unless irritated, is free from sensation.

Chancre begins with itching, followed by shooting, aching, or a sense of burning; but, in general, the uneasiness, unless the sore is touched, is so trivial as hardly to excite attention. The pain, of course, bears a proportion to the quantity of inflammation and ulceration; but, nevertheless, in cases intermediate to the extremes which I have described—as in the ulcer spreading from neglect, the surface covered with dark-coloured secretion, the surrounding textures swollen and red, “the foul and angry sore, with ragged edges,” spoken of in narrations of cases—the pain is a most variable element.

The special accidents of primary syphilis are two, phimosis and bubo.

PHIMOSIS.—By phimosis is meant any condition of the prepuce which prevents its retraction. So, simple venereal induration of a large portion of the outer prepuce, or indurated chancre of its inner surface (p. 240), produce one form of the complaint.

Those which remain for consideration are of three kinds:—

1. Congenital phimosis, with ulceration within the prepuce.—Congenital phimosis results from the inner surface of the extremity of the prepuce forming an undilatable ring too narrow to allow of its retraction. This does not necessarily prevent venereal infection. A patient whom I attended had had for several months a discharge of matter from within a natural phimosis. During the last few days the part had become rather tumefied; the glans was sore on pressure, and the edge of an ulcer could be distinguished upon it, near the orifice of the urethra. The patient was directed to syringe the part with warm milk and water, to remain in his apartment, and to take aperient medicine. When two days had elapsed, the soreness being increased, I divided the prepuce, and exposed a superficial ulcer, with irregular edges, occupying half the glans. The wound of the prepuce healed before this sore cicatrized. My principal object in dividing the prepuce was to remedy the natural phimosis; the spread of the sore would probably have rendered it afterwards necessary on other grounds.

Sores, not siphilitic, casually formed

upon the inner surface of the extremity of the prepuce, when that part is long, are sometimes prevented healing by the irritation of the urine. After a time the texture round them becomes hard and callous, forming a *ring* like that of natural phimosis, and the sores become exquisitely sensible, and the passage of the urine gives intolerable pain. At the same time there may be no general swelling or inflammation of the prepuce. In this case, the ordinary soothing means failing, it may be necessary to divide the prepuce, so as to allow it to be drawn back, and the sores out of contact of the urine. I not long ago had to divide the prepuce under these circumstances: the patient had been suffering for several weeks previously. I found three shallow ulcers at the place of constriction, with no inflammation round them, but the cellular texture and skin firm as cartilage.

3. The third and common source of venereal phimosis is general inflammatory swelling and tenderness of the prepuce, with discharge from within. If this state of parts has supervened subsequently to the patient coming under treatment, the case is much simplified.

4. If the cause is known to be inflammatory excoriation, or secretion of matter from the surface of the glans and inner prepuce, injections of tepid milk and water, to cleanse the part, and of a saturnine and opiate lotion, with maintenance of the horizontal posture, the part being kept supported, with abstinence in diet and cooling medicines, are the appropriate remedies.

If the cause is chancre, the same local means, with the occasional injection of the calomel and lime-water lotion, are to be adopted, and mercury given.

If phimosis supervenes on virulent phagedæna, the prepuce should be divided, for the reasons explained at page 191.

When inflammatory phimosis with discharge exists, and the patient can give no account of the state of the parts within, there may be room to doubt what course should be pursued. But the operation of dividing the prepuce ought not to be performed if it can be avoided; and it is not immediately necessary unless virulent phagedæna is present; and the latter is not present unless the discharge, in place of being purulent, is thin and ichorous, or sanious and profuse, often highly offensive, with

severe pain, and the prepuce swollen, and of a deep red; at one part or another, perhaps, mottled, with lividity. In the latter case the prepuce should immediately be laid open; and even in less virulent disease, where phagedænic ulceration is more slowly eating away the glans, the division of the inflamed prepuce, to expose the ulcerating surface for the application of proper remedies, may become necessary. In this minor degree of severity we may suppose that the phimosis will yield enough to allow the glans to be sufficiently seen to judge of its state.

The following case, which was communicated to me by Mr. Druiitt, exemplifies severe inflammatory phimosis, not connected with phagedæna, and its proper treatment:—

A confectioner, aged 30, of a full habit and florid complexion, applied for advice with the integuments of the penis greatly swollen, especially the prepuce, the end of which was in colour a dark red. The glans, as much of it as could be seen, was covered with a yellowish white secretion, which came off in flakes. There was abundant purulent secretion, which poured out from below the prepuce when it was pressed; the discharge was principally matter, but the flakes above mentioned, and blood, were mixed with it, and it sometimes came out thinner and sanious. There was constant gnawing pain. He had considerable symptomatic fever, headache, pain in the back, furred tongue, hot skin, frequent hard pulse. He would not submit to be bled, but he consented to go to bed, and took aperient medicine and salines, with antimony, and injected repeatedly tepid decoction of poppies below the foreskin, keeping the part at night in a poultice of camomile flowers. He mended quickly, and was allowed to leave his bed in five days, the swelling, discharge, and soreness, being much lessened, and the pain gone. The cure was completed by means of astringent injections. When, at the expiration of three weeks, the foreskin could be drawn back, the glans was of a bright red. The whole surface had been in a state of inflammatory excoriation. The phimosis had existed some days before his treatment was commenced, and he had taken mercurial pills during three; they were discontinued.

BUBO.—The term *bubo* denotes a phleg-

monous inflammation of the lymphatic glands of one or more of the surrounding cellular tissue, in a region adjoining the primary sore. When the chancre is on the genitals, the bubo occurs in the groin.

This disorder arises, it is presumed, in some instances, from sympathetic irritation alone, or in the same manner that it is known to follow any accidental sore upon the skin, or gonorrhœa; but in many instances it certainly directly results from the absorption of the syphilitic virus.

There are two periods at which bubo is most liable to supervene. The one is within a few days after the appearance of the ulcer; the other when the ulcer is losing its specific character, and beginning to change to a granulating sore. Intermediately bubo frequently arises; but it is then often traceable to some indirect cause, such as walking or riding, by which the sore may have been chafed. The commencement of a course of mercury has a tendency to bring forward buboes that were before indolent.

The commencement of bubo is generally slow: a gland is felt to be enlarged, of the size, perhaps, of a Spanish nut, and is sore when pressed, or in walking, or upon change of posture; then the surrounding cellular tissue becomes engaged, and there is a firm doughy swelling containing and concealing the gland itself. The integuments are hot, and sore on pressure, but not discoloured. The progress of the complaint is most uncertain; sometimes, with great pain, and aching, and soreness, and burning, and pricking, the swelling runs on to suppurate in a few days; and matter may be felt to exist, while the skin is red for a short and narrow space only. In other cases the tumor remains indolent, while the skin becomes for the extent of two square inches or more of a dull red, and has an elasticity like matter forming; and tumors such after all quietly disperse.

When the swelling in the groin is first perceived, of all things rest is to be strictly observed, and no irritating applications are to be used to the sore. To the tumor itself cold embrocations are at first the best, such as the liquor plumbi subacetatis dilutus, or a weak spirit lotion. When the application of cold is grateful, the part may be bathed

with iced water occasionally during the day. In this manner I think I have seen buboes put back that else might have suppurated. Care is to be taken not to chill the patient through such applications, which are to be strictly local, and to be made for a short time only. When warm fomentations are more agreeable to the patient's sensations, they are preferable, and an anodyne poultice in that case may be recommended. Whatever lessens the uneasiness tends to reduce the inflammation; whatever reduces the inflammation lessens the chance of matter forming.

If possible, a bubo should be repelled: even when matter has formed, there is still a chance of its reabsorption; but the means which can be employed to promote it are limited to rest, cold embrocations, and poulticing.

If there is much pain and heat, and the symptoms have progressed rapidly, and the fluctuation is distinct, the bubo had better be opened without delay. If the red surface is of small extent, the opening may be made with a lancet: it had better not be much less than an inch in length, but it should not extend beyond the thinned portion of the integument. If the quantity of inflamed skin is considerable, and it is undermined to some extent, the fluctuation being distinguishable for that extent, and the inflamed integument thin, the bubo should be opened with caustic. For this purpose you rub with a stick of potassa fusa a surface of the size of a sixpence or larger till its vitality is destroyed; a poultice being then applied, in a few hours the abscess opens at the edge of the slough. This method is preferable to puncturing with a lancet, inasmuch as it gets rid at once of a portion of the inflamed and undermined skin, which otherwise would have disappeared more slowly by ulceration, retarding the cure.

When a venereal bubo has been opened, in many instances its progress is favourable: the discharge gradually lessens, the cavity fills up, and the granulations joining those of the edge of the aperture, cicatrization takes place within a few weeks. But in other cases various troublesome consequences will follow. M. Ricord found that inoculation from the matter of venereal buboes will produce chancre; but he curiously observed, that the matter used

must not be the matter that flows out first, (or that from the suppurating cellular tissue), but matter taken from the bottom of the abscess, (that is to say, from the suppurating gland itself): the next day the two are mixed, and the general matter will infect.

This observation tends to establish some remarkable points. In the first place it proves that bubo is sometimes caused by the actual absorption of the siphilitic virus. In the second place, it establishes that such buboes are parts of the disease, and that an open bubo may be a venereal sore. But I was not prepared by it for an additional conclusion, which nevertheless one might have anticipated, and which the circumstances of the following case sufficiently establish. A young man became my patient with indurated chancre on the inner prepuce; he took mercury, and his mouth became sore. The chancre in a fortnight had improved in appearance; but a bubo, which had been threatening some time, now came forward. A month from the commencement of the mercurial course the chancre was a healthy ulcer covered with granulations, and its edge cicatrizing; but the bubo had become more painful, and evidently contained matter, though the skin was reddened to a very small extent. I therefore opened the abscess with a lancet, and with the last quantity of pus which flowed inoculated this patient on the arm. Three days afterwards the point inoculated became a pustule, and then a chancre; at the same time the opening made in the bubo assumed exactly the same character, acquiring a determinate, raised, and inflamed border, and the two sides of the aperture perfectly resembled the surface of a chancre. For this inguinal chancre I have judged it right to continue the mercurial course. We may hence infer that matter formed in a bubo from chancre is not changed in its nature by a course of mercury, but that it remains capable still of infecting. It unavoidably follows, that siphilitic buboes that have suppurated should be opened early; that if opened late by art, or spontaneously, the character they present should be carefully attended to. That if opened late, opening by caustic is preferable to opening with a lancet, as an ulcerated surface probably takes contagion slower than a cut surface. Finally, it is evident that the possibility

of this re-infection from the matter preserved in an unopened bubo, throws additional difficulties in the way of determining the efficiency of mercury as a preventive of constitutional lues.

One of the most troublesome consequences of bubo is the formation of fresh suppurations in the adjoining cellular membrane, which open into the original abscess, and, contracting, leave long subcutaneous sinuses, which are often of most tedious recovery. These are to be treated with the mildest applications till the course of mercury is finished, and the patient's health has recovered its tone; then by the injection of stimulant washes and pressure, and, if necessary, by laying them more or less extensively open, they may be healed; but division of such parts is to be shunned, if possible, from the danger of exciting new inflammation of the adjacent cellular tissue.

An open bubo is liable to the super-vention of phagedæna; its surface becomes glazed; it is hot and painful; its edge angry, irritable, ulcerated, or sloughing. The relinquishment of mercury, if mercury is being administered, opiate poultices to the part, opium administered internally, with such other remedies as the patient's general condition demand, are the means to be recommended.

If the bubo extends in depth, its situation near the femoral artery renders the disease extremely alarming, and likewise renders any decisive measure, such as cauterizing its surface with nitric acid, impracticable. When it spreads at the edge alone, the ulcer, as in a remarkable case given by Hunter, is liable to be exceedingly unmanageable. Tonics, sarsaparilla, with the iodide of potassium, change of air, and of local applications, are the likeliest means to arrest its spread. After these have been exhausted, recovery of a sudden will perhaps spontaneously and unaccountably take place.

Sometimes a bubo will remain a length of time stationary and indolent, with a thickened, callous, irregular edge. If the application of mercurial lotions, or Peruvian balsam, will not induce action in it, the callous edge should be destroyed by rubbing it with the potassa fusa; then, after poulticing to separate the sloughs, pressure by bandaging will certainly compel it to heal.

The lymphatic vessels of the penis are sometimes inflamed in chancre, and may be felt as firm and tender shreds below the skin. Occasionally little abscesses form in these, the matter from which M. Ricord found capable of communicating chancre.

## II. CONSTITUTIONAL LUES.

Constitutional lues is a condition of the system produced through the absorption of the siphilitic virus, and manifested by the invasion of a series of disorders, which, although very dissimilar in different instances, are yet so strictly connected by common origin, occasional coexistence, and obedience to the same remedies, as to form indisputably but one disease.

The secondary symptoms of siphilis are—eruptive and ulcerative complaints of the skin and throat, inflammation of the iris, nodes upon the bones, with other affections of less consequence and of rarer occurrence. When the disorders so enumerated attack the same individual, the order of their appearance is commonly that in which they have been named.

The duration of constitutional lues varies from one to two years; sometimes the disease appears to be cut short after a single attack,—sometimes it persists for several years. During its whole continuance the patient is below his former average of strength and condition. But he is not for the same period exhibiting special symptoms: the disease has remissions, which are often so complete as to lead to the belief that it is cured when it is not; nevertheless, there are instances in which the disease, left to itself, continues indefinitely progressive.

The first attack of secondary symptoms generally takes place between two and three months from the commencement of the primary disease: I have known it, however, happen within three weeks after chancre has been discovered, and I have known it, again, delayed upwards of a year; and in one instance the patient assured me that four years intervened between the secondary disease and any primary venereal complaint. The invasion of constitutional lues is shown in cases where the previous treatment has been mercurial.

The differences in the march of the disease, which I have specified, are not referable to differences in the character of the primary ulcer. They arise from

peculiarities in the habit of the persons infected; in other words, from individual predisposition—the same cause which determines the character of the primary disorder, the greater susceptibility towards it of one individual over another, the different susceptibility in the same individual at different periods of his life. The influence of this cause modifies the disease in entire communities, changing its features in the inhabitants of different countries. So in Portugal the disease is milder than in England: and in Dublin, Mr. Carmichael mentions that papular venereal eruption is common, and scaly eruption rare: whereas in London, psoriasis is certainly more frequent than lichen. Lapse of time tends, again, it is presumable, to alter the disposition towards the disease in the same people. Its original great outbreak at the close of the fifteenth century was probably owing to some sudden and general heightening of the susceptibility throughout Europe towards a poison, probably always existing, possibly among the secretions of health. The general modifications which siphilis has undergone, and to which Astruc assigns determinate periods, have been regulated by the same cause. The same cause may produce its disappearance, or again render it more virulent still, and the remedies we now employ against it inert and nugatory.

By the observance of extreme moderation in diet, in bodily exercise, in mental exertion,—by avoidance of every thing calculated to heat, excite, disturb, or even invigorate the system,—constitutional lues may be so kept under that in the mildest cases the continuance of this disease will only be known by the slightest occasional manifestations, requiring no special treatment.

In cases next to the mildest, the secondary symptoms of siphilis require medicine for their control, lest temporary or permanent impairment of organs or disfigurement take place. The principle to be followed in the greater number of such instances is to aim at subduing the present attack. The ravages of siphilis that are read of, and occasionally seen, have arisen from the injudicious attempt forcibly to eradicate the disease when already in its secondary form, mercury being used as the agent. Mercury, however, is essential in the treatment of particular classes of secondary symptoms—of iritis especially; but in the

greater number it is either unnecessary or injurious, and other means are preferable.

Nevertheless, there is room for stating, as a third principle, that in a few instances the disease, in its secondary form, admits of being extinguished by a protracted course of mercury. The instances, however, in which alone I think there has been reason for believing this result to have taken place, have existed a long time, where, notwithstanding occasional remissions, it has been progressively aggravated, and in which mercury has not been given in it for a long period or at all.

Of the remedies for constitutional syphilis, mercury is so far the most important, that is the only one, however rarely it may be right to use it with this object, through which the extinction of constitutional lues can be anticipated; and that besides, as a palliative of the disease, it is one of the most efficacious. The other remedies are exclusively palliative, or are capable only of removing the present attack; nevertheless they are the most proper in the majority of instances, and in the most painful and disfiguring forms of the malady they alone have power to control it.

The remedies that are palliative alone are first the iodide of potassium, then sarsaparilla, the compound decoction, or its infusion in lime-water; and the decoction of *smilax aspera*: with the three last, liquor potassæ may be joined; then nitric acid in decoction of bark, and the sulphate of quinine with dilute sulphuric acid.

The iodide of potassium is by far the most efficacious among these palliative remedies. It may be given either in pills or in solution. When given in pills, they should be washed down with half a tumbler of barley-water or toast and water, or with three or four ounces of compound decoction of sarsaparilla. Those to whom the taste of the iodide is not nauseating, had better take it already dissolved in the decoction or infusion of sarsaparilla. The iodide of potassium is sometimes efficient in doses of two grains, three times a day; generally, however, from five to ten grains, or even twenty, are necessary. But unless, from recent trials, the patient knows that the medicine perfectly agrees with him, it is best to begin with a smaller dose. No medicine, perhaps, where it does good, produces amend-

ment so speedily as the iodide of potassium; therefore the propriety of continuing it is never doubtful: it is useless to continue it at the same dose, when no sensible progress is made by the patient; so it is often necessary to increase the dose, and to go on increasing it. I have, in a few cases, been so led to administer as much as half a drachm of the iodide with a grain of iodine, three times a-day, having obtained an amendment at each increase of the dose up to this quantity. The evanescent character of the influence of this medicine is most remarkably shewn by the advantage derived from using it with intervals, discontinuing it for a fortnight or a month, and then resuming it. If the disease had become stationary when the iodide was discontinued, and got worse during its intermission, on returning to its use the symptoms seem to disperse miraculously. The principal use of the other palliative remedies which I have named is to fill up, if necessary, the intervals in which the iodide requires to be discontinued, to regain its efficiency, or in cases where it disagrees. They appear to exert a feeble influence of the same kind.

The only sensible effect of the iodide of potassium, where it fully agrees, is an increase in the quantity of urine. It is liable to disagree in the following ways:—With some it disorders the bowels; with others it produces uneasiness at the stomach, and an acrid dryness of the throat; in others headache. Each of these disorders, however, will sometimes admit of being rectified by adding a few drops of laudanum to each dose, aperient medicine being at the same time administered, especially when headache is the symptom to be contended with. I have heard of, but have not seen, depressive effects, analogous to mercurial erithismus, being produced by this medicine. Of course, in that case (as in the others, if the disorder persist), the use of the remedy must be abandoned.

In some cases, mercury and the iodide may be most advantageously combined; a pill of corrosive sublimate and bread being taken, for instance, with each meal, and the iodide of potassium in sarsaparilla intermediately. In one case, where two forms of eruptive disease were simultaneously present, it was evident that the two medicines thus exhibited controlled each one of the former:

so that on either remedy being omitted, the corresponding eruption made head.

Having premised these general observations on the nature and treatment of constitutional lues, I shall proceed to describe the various disorders to which it gives origin, ordering my account of them in such a manner as will permit me to group and display together those sets of symptoms which constitute several forms of secondary syphilitic disease.

The first attacks of the disease are commonly made upon the skin and throat simultaneously; and the affections of both parts display, in that case, a corresponding character. But sometimes the skin alone is affected, at other times the throat; and commonly a difference is shaped in the disease by the predominance of either complaint: therefore it is better to describe the two separately, and I shall begin with the skin.

Syphilitic affections of the skin may be practically divided into the non-ulcerative and the ulcerative: the first division includes roseola, mottling, psoriasis, lichen; together with a vesicular eruption, and some soft tubercles which do not ulcerate. The second comprehends lepra, tubercle, cethyma, rupia. The objection to this arrangement is, that psoriasis occasionally leads to ulceration, and that lepra may commonly be prevented proceeding thus far: nevertheless, the usual tendency of each of the two eruptions in some degree justifies me in separating and placing them as I propose to do. Syphilitic sore throat presents four varieties—excoriation, superficial ulceration, excavated ulcer, sloughing ulcer.

I shall now describe the appearances presented by roseola, mottling, and psoriasis; previously to exemplifying the first and commonest form of secondary syphilis, of which the last named constitutes the prominent feature.

*Syphilitic roseola* is an efflorescence of a bright red colour, more inclining to a coppery than to purple red, which occasionally appears upon the belly and thighs, as the first attack of constitutional syphilis. It lasts two or three days only, during which it varies in brightness of colour, and, becoming pale, disappears entirely. Sometimes slight symptomatic fever attends it.

*Maculata syphilitica*, or mottling, may be divided into two kinds—simple and leprous.

In the first the skin is mottled, with patches of irregular size and indeterminate outline that are of a brownish-red colour, the one tint or the other predominating. This mottling usually appears first upon the lower part of the abdomen and upon the loins, sometimes extending to the thighs; and it sometimes moves from the loins to the chest. Upon the face and forehead it has a dull leaden hue, and the integument looks thickened or swollen, when it is present.

The term leproid or leprous maculatum, I venture to use for a similar colouring, when the edge of each spot is defined and circular: this is not a very uncommon appearance; I have seen it upon the whole of the trunk and forehead, the circular spots being about a third or two-fifths of an inch in diameter. In one patient, upon the forehead was a large circular patch of this description, one-half of the edge of which was redder and slightly thickened, but perfectly smooth, forming a thin raised semilunar border.

Mottling is probably produced by the same action upon the skin with that which goes on to form psoriasis, or lepra; but it is less in degree; is, with rare exceptions, not elevated; and does not sensibly desquamate.

*Psoriasis syphilitica*.—The eruption consists of small raised patches of inflamed skin, with lymph effused under the epidermis, which separates in scales. In Willan's plates, under the name of psoriasis guttata, the common appearance of the eruption is very faithfully given. The first appearance of the eruption is as a small raised red point, that spreads, in two or three days, to its full size, which varies from a quarter to a third of an inch in diameter. The figure is sometimes strictly circular, more generally irregular. The elevation is greatest on the middle of the patch, and slopes to the edge. The degree of elevation, and the disposition to throw off scales, is different in different cases, and the character of the eruption varies in different parts. On the head it is often acuminate; on the forehead it is slightly raised at first, but becomes flat as it becomes broader. On the chest and back it is elevated and convex; on the lower part of the abdomen, broad and flat; towards the pubes it has a tendency to run into large flat patches, with cracks, from which serum oozes and dries, forming a slight crust. Upon the glans penis it forms a superficial and

circular sore or patch of excoriation; on the scrotum a raised tubercle; on the sides of the scrotum towards the groin, between the nates, in the axilla, the patch is raised, soft, and sore, and moist with exuding serum. Upon the hand, psoriasis sometimes appears in numerous circular or convex patches, covered with horny cuticle; but more commonly there are but one, two, or three patches, which at first are small and elevated, then spread to a large size, becoming flat, with an irregular outline, looking alternately red and covered with desquamating cuticle, and exhibiting cracks. At the ends of the fingers it forms with acuminate brown patches by the side of the nails, which sometimes are shed; when a patch invades the secreting surface. The disorder occurs in every degree, from a single patch on the hand to an eruption looking not unlike the vesicular stage of small-pox over the whole person. In fading, each patch leaves a light-brown stain, which gradually dies away. Sometimes, but rarely, a bright yellow coppery stain is left, which does not completely disappear for months.

The eruption, as I have described it, whether scarce or abundant, may be called psoriasis guttata sparsa. Sometimes it exists in groups alone, of forty or fifty such patches, covering a space of two or three square inches. Upon the loins and back, four or five such groups may form. This variety may be called psoriasis guttata agminata. It has a tendency to go into ulceration, which the other rarely exhibits.

[To be continued.]

## SMALL-POX AND VACCINATION.

DR. CONOLLY IN REPLY TO DR. GREGORY.

*To the Editor of the Medical Gazette.*

SIR,

DR. GREGORY having confined himself in his first letter to pointing out *one* mistake in the Report of the Vaccination Section of the Provincial Association, which Dr. Baron acknowledged and corrected in the succeeding number of the MEDICAL GAZETTE, commences his second communication (the tone of which is not to be commended either for its candour or courtesy) by supposing that there *may* be many other errors of the same kind in the Report, not any of which, however, has he pointed out.

Dr. Gregory professes himself to be at a loss to conceive how the results of Mr. Ceely's experiments are to remove prejudices. It is true, as Dr. Baron has observed, these experiments only corroborate the opinions of Jenner; and confirm those of M. Viborg, Professor of the Veterinary College, Copenhagen, of Dr. Waterhouse, of Cambridge, Massachusetts (see Life of Jenner, vol. 1, page 441) and of Dr. Sonderland, of Bremen (see MEDICAL GAZETTE, for November 5, 1831). That prejudices did, however, still exist, and that the identity of cow-pox and small-pox were not proved to the satisfaction of every one, is well known; in proof of which, I would refer to a letter which appeared in the MEDICAL GAZETTE of January 7th, 1832, signed George Gregory, in which the writer expresses very strong doubts upon the subject, and says (speaking of the experiments of Dr. Sonderland) "the whole affair seems to me to savour very strongly of a romance." In the same letter he throws blame on Dr. Baron for having claimed for Dr. Jenner priority on a "theoretical question, involved in so much doubt, as the identity of small-pox and cow-pox;" he then proceeds to say, "nothing short of the direct transmission of the disease from man to animals, and from animals back to man, can (in my mind) justify the position that cows are liable to small-pox; and where, may I ask, are such experiments recorded?" Yet now, when such experiments have been undeniably recorded, with admirable inconsistency Dr. Gregory says, "the interesting fact recorded by Dr. Sonderland" (the fact which he had eight years ago treated as romance) "is demonstrative of the truth of the conclusions which have been mentioned." The real truth being, that Mr. Ceely's experiments are so conclusive, that even Dr. Gregory can no longer doubt the identity of the two diseases, which he now insinuates was proved eight years ago by Dr. Sonderland; the fact, however, is, that this important question *did* remain doubtful in the minds of many persons, until the success of Mr. Ceely's experiments proved it to demonstration. It will not do to affect to treat this interesting result lightly, and for the same person to tell us now, that the pathological question is of no importance, and that the establishment of a general penny postage "will do more to secure correct and satisfactory practice, than the solu-

tion of twenty pathological problems," who told us eight years ago that these self-same pathological questions were of "vast extent and importance."

Mr. Ceely was led, I believe, to make his experiments by the statements of Dr. Baron, contained in the first volume of the *Life of Jenner*; statements which to many minds were demonstrative and convincing. The real value of these experiments (conducted as they were in so careful and skilful a manner) may, I think, be very safely left to the judgment of the profession; they have placed beyond all doubt the truth of opinions originally held and promulgated by Jenner himself, and energetically enforced on all occasions by Dr. Baron, but constantly opposed and denied by Dr. Gregory.

I beg to refer any one who may be unacquainted with these facts to the volumes of the *MEDICAL GAZETTE* for the year 1828, more especially to Vol. II. for that year, page 79, where Dr. Gregory distinctly asserts his belief in the impossibility that two persons exist who believe in the common origin of cow-pox and small-pox. Is it not unjust, then, in him now to taunt Dr. Baron with bringing forward Mr. Ceely's experiments, as triumphant proof of all he had before asserted; and telling him that if the former facts were true, those of Mr. Ceely's are but "surplusage?" Surely in all questions of medical science every additional fact is of value.

The communication of your correspondent "Scrutator" bears such evidence of personal pique and ill-will towards Dr. Baron, that it would not be deserving of notice, but that it affords an opportunity of explaining a circumstance that may have excited surprise in the minds of others as well as in that of Scrutator. He charitably supposes that the reason so little is said in the Report of the statement from the Small-Pox Hospital is, that it "was not so favourable to the cause of vaccination as Dr. Baron wished." This supposition is as false as it is uncharitable. The motives which influenced Dr. Baron are well known to me, and were such as do him honour, viz. great delicacy towards Dr. Gregory, and a desire to avoid every thing which might lead to controversy. I know that in the original draft of the Report, the return from the Small-Pox Hospital was noticed at considerable length, and scrutinized; and that upon

re-consideration Dr. Baron himself erased this portion of the Report, fearing that it might wound the feelings of Dr. Gregory; anxious to avoid doing so at all times, but more especially at a moment when he was understood to be labouring under the pressure of domestic affliction.

In the statistical table of the Small-Pox Hospital, drawn up by Dr. Gregory, and presented to the Section, 103 persons are reported to have died of small-pox after vaccination, between the years 1820 and 1839. This is a fearful statement; but upon examination we find that in the year 1825, a year in which small-pox was unusually prevalent in London, twelve deaths are reported to have occurred in the Small-Pox Hospital after vaccination. It appears that this alarming statement excited, as soon as it appeared, the attention of the Secretary of State, who desired the National Vaccine Board to inquire into the matter; and to their questions Dr. Gregory replied, (*vide Medical and Physical Journal*, for May, 1826) that in eleven out of the twelve cases, the characteristic marks of vaccination were wanting, and added, he believed that they might as well not have been vaccinated at all. Notwithstanding, these twelve cases are allowed to figure in the statement presented to the Section, in 1839, as cases of death from small-pox after vaccination; whereas, one of these cases only can with any propriety be so considered; and this is a year when, to use Dr. Gregory's own words, in a communication to the *Medical and Physical Journal* for February, 1826, "the admissions into the Small-Pox Hospital have been greater than in any year since 1796." It appears that during the year 1825, 147 cases occurred at the hospital after real or presumed vaccination, of whom as before stated 12 died; and two had it subsequently to various inoculation, of whom one died. In the statistical table, twelve deaths are again recorded to have occurred in the hospital after vaccination, in 1832; ten, in 1836; and eighteen, in 1838. But I would ask what faith could possibly be placed in returns conducted in such a loose and careless manner as these are proved to have been? Every case of reputed vaccination, and where confessedly the characteristic marks were wanting, being returned as cases of small-pox after genuine vaccination.

Again, Dr. Gregory, in his examination before a Committee in the House of Commons, May 9, 1833, gave in a "Return of the number of cases received into the Small-Pox Hospital, having small-pox subsequent to repeated vaccination, for seven years, ending December 31, 1832." In this return 319 cases are reported as having had small-pox after vaccination during the seven years, of whom forty are reported to have died. This report was given in to the Committee, without the slightest qualification whatever. Yet, when Dr. Gregory was questioned by the Committee upon these cases, it was elicited, that out of the forty who died, seventeen only had good scars, or characteristic marks of previous vaccination; and that several of the forty who died, "died of erysipelas, or laboured under some other disease co-existing with the small-pox!"

Now let it be observed that in the statistical table sent in to the Vaccination Section of the Provincial Association, Dr. Gregory reiterates the statement, with regard to the twelve and the forty cases, without one qualifying observation whatever. Under such circumstances, and after such repeated proofs of inaccuracy, was it possible that the Section could attach much weight to them in their report; especially as the evidence was so completely contradicted from every other quarter?

The whole history of the Small-Pox Hospital, as far as vaccination is concerned, has been most unfortunate, beginning with the mistakes of Dr. Woodville, in 1799, and in my opinion fully justifies the reserve that has been maintained in speaking of it in the report.

Scrutator complains that Dr. Heim's work has been passed over in a cursory manner. The business of the Section was to report upon the answers received to certain questions circulated amongst the practitioners of this country, and it did not, of course, come within the scope of their plan to give much space to continental statements. Besides, many might be of opinion that Dr. Heim's inquiries, elaborate and interesting as they are, had for their object to discover differences between the variolæ of man and the inferior animals, rather than to establish affinities, which is now shewn to be the correct mode of investigation. Independent of which it was not considered to be the duty of the Section to

repeat statements which were already in print, unless they were of a very important nature, and established some great principle. It is manifest that a discretionary power must rest somewhere, and the views entertained by the Section on points of this kind are clearly set forth in the preliminary observations of the report, and I think they are correct. (Vide pages 7 and 8 of the Report).

Scrutator expresses his belief that small-pox after small-pox is of very rare occurrence indeed. If he extends his inquiries I think he will change his opinion; many cases are recorded in the answers to the inquiries of the Section; within the last 18 months I have myself known several instances, and one of which was fatal.

Speaking of Dr. Baron, Scrutator says, "we have had enough of his laudation of Jenner year after year; we want now to arrive at the real merits of vaccination." Now, sir, I contend that we have arrived at the real merits of vaccination, and that they are fully stated in the Report; and I am one who thinks we can never too much laud that great and good man, and sound philosopher, whose discovery has proved such a blessing to the whole human race—who has never yet had justice done him by his own country, but whom, I doubt not, generations yet unborn will hail as one of the greatest benefactors of mankind.

I have done with Scrutator; if he wishes any further inquiries answered, let him throw aside his mask, and come forward in a manly and generous manner, and I doubt not but he will be met in the same spirit.

I am, sir,

Your very obedient servant,

WILLIAM CONOLLY.

Castleton House, near Cheltenham,  
Nov. 11, 1832.

P.S. Nov. 19th.—I have just seen the letter of Dr. Gregory in the last number of the GAZETTE. He seems to think it can be of no importance to your readers what he said at Liverpool upon the subject of the Report; but as every thing he said there is utterly at variance with what he is writing now, he is bound, I think, to explain the apparent inconsistency of his conduct. It is in vain to talk about the "courtesies of society," the "time allotted for discussion," or "the hour appointed for dinner;" these matters had nothing to do with it. Courtesy might have induced Dr. Gregory

to remain silent if he did not approve, but could not render it necessary that he should be so insincere as to declare his cordial approval of the Report, and to move or second its adoption, or to indulge in such a strain of eulogy upon Dr. Baron and his labours, as he did before the assembled Association.

MR. COLES IN REPLY TO DR. GREGORY.

*To the Editor of the Medical Gazette.*

SIR,

I PROBABLY should not have written on the subject of the Vaccination Report, had I been aware that Dr. Conolly had taken up its defence; because he is far more fitted for it by his talent, and official situation as one of the secretaries, and it seems to me needless to overload the question with vindications. I should not now trouble you with additional remarks, did I not heartily dislike the appearance of making a great prelude flourish, and then taking myself off, and quitting the field of contest altogether; but I beg you to postpone the insertion of this communication if its length interferes with the appearance of Dr. Conolly's promised letter.

Ever since the discovery and application of the prophylactic agency of cow-pox, two opinions respecting its nature have prevailed. A great part both of the medical profession and public have regarded it as a disease distinct from small-pox, and only related to it in the way of an antidote of great, but at the same time undetermined, and therefore doubtful efficacy. By patient and accurate investigation of variolous diseases in man and animals, Dr. Jenner arrived at a different conclusion, and discovered that they were essentially one and the same disease. Dr. Baron amply confirmed the truth of this original discovery in his elaborate historical research into epidemic and epizootic diseases, and, more emphatically than the discoverer, promulgated it as a most important doctrine. This doctrine has received additional confirmation (not to mention other corroborative facts) from the experiments of Dr. Sonderland and Mr. Ceely; the former proving that small-pox effluvia, and the latter that small-pox inoculation, can produce in the cow genuine cow-pox. Each additional proof of a doctrine will tend to

increase the number of converts to that doctrine, and diminish the doubts of those who remain unconvinced; and a man may resist all the evidence of the identity of small-pox and cow-pox, up to Ceely's experiments, and be converted by them at last: of which truth Dr. Gregory affords an illustration in his own person. There are medical men at this moment who have but little confidence in vaccination as an antidote, but place great reliance on variolous inoculation; and others who think the security bears a proportion to the amount of local irritation, and practise vaccination in accordance with this theory. Now the demonstration that there is but one disease must tend to remove such prejudices; and would lead to the conviction that the prophylactic powers of vaccination and variolous inoculation are on a par: whilst correct and satisfactory practice would be likely to be secured by the recollection that in small-pox inoculation one pustule affords equal immunity with several. In this way, then, do Mr. Ceely's experiments support the conclusions objected to by Dr. Gregory: but it ought to be remarked that the Report merely asserts that "the right understanding of this question," (viz. the identity of the two diseases) will produce these results, although Dr. Gregory has, with singular alacrity of misstatement, transferred this assertion to Mr. Ceely's experiments.

With respect to Dr. Gregory's reasonings, I do not think it worth while to expend a quantity of paper and type in analysing and refuting them. I would rather say to any one who takes an interest in the controversy, deliberately and carefully read Dr. Gregory's letter again and again; turn up for yourself the places quoted, and mark well the context; and then test Dr. Gregory's conclusions and inferences by the ordinary rules of logic, or the dictates of common sense. If you are not one of those who approve of wrenching fragments of sentences from their contexts and wresting them from their obvious meaning—if you do not confound the distinction between what actually is and what reasonably ought to be—if you do not cavil about demonstration in matters which admit only of cumulative proof—if you are not one who refuses to perceive when an author speaks of the doubts of others and not of his own—or if you are one that will not be beguiled

by a dilemma founded on the palpable misapplication of a word,—then, the best refutation of Dr. Gregory's arguments I can offer you is to ask you carefully to read them. It would take at any time almost the space of a pamphlet, to unravel and expose a page or two of clever mystification; and the labour would be very ill applied, since few, and perhaps none, would care to read any lengthened and minute refutation. No wonder, then, that persons generally shrink from controversies of this kind, particularly when they observe that it commonly happens that not the possessor of substantial truth, but the greatest proficient in refined *Billingsgate*, fares the best in these encounters. I have no wish to trouble you with further observations on this subject. Dr. Conolly will deal with the material topics of Scrutator's letter; and although there are points deserving of rebuke, I would rather leave them to the silent censure of the well-judging.—I am, sir,

Your obedient servant,

HENRY COLES.

Cheltenham, Nov. 11th, 1839.

## MEDICAL GAZETTE.

*Friday, November 22, 1839.*

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."  
CICERO.

### SUPPLY OF SUBJECTS FOR DISSECTION.

THERE is one subject for our remarks which for some years past has regularly recurred at this season, and has each time brought with it the demand for plainer and stronger expressions of rebuke: we need scarcely say we allude to the supply of bodies for dissection; which under the present system of management is yearly becoming a source of greater annoyance to both teachers and pupils. The statements necessary for the exposure of the faults of the plan by which subjects are supplied, are so plain, and so few are needed to prove its insufficiency and its mischievousness, that it is impossible but that our annual

remarks should be chargeable with tautology. Still, as the blows we have already given have not been without effect, we are induced to persevere, and essay, with the same weapons of truth and common sense, used in the same manner, to bring the system to the speedy end which it deserves.

Within the last recess, measures commenced some time since have been urged with increased force to place the business of obtaining subjects under the management of the Council of the College of Surgeons; a body every member of which is either personally or at least professionally deeply interested in securing a supply adequate to the wants of the students. Amongst all the teachers of anatomy, two only have been decided dissentients from this plan, and of these one, we understand, has already withdrawn his active opposition.

The objections urged against the transferring the duty of obtaining the supply from the present Inspector (upon whom, be it remembered, this office was forced, in addition to that to which he was originally appointed) to the College of Surgeons, all centre in the suspicion, that as many of its members either are themselves, or have connections who are, teachers at hospital schools, they might act unfairly towards the private schools, whose interests are not represented in the Council: in other words, that the members of the Council would serve their own interests, by obtaining a good supply for their own schools, and by injuring as far as possible the interests of their opponents.

Now as this opinion has been expressed by those who are on terms of personal and professional intimacy with the members against whom they feel it, it will matter little to urge the improbability that those who are deemed gentlemen, and honourable in private life, and in all their transactions as

medical practitioners, should be guilty of a fraud like this; of such a dirty, dishonest practice, as might justly exclude them from the right of being received into respectable society. This improbability can be of little avail as an argument against the belief of those who can have such suspicions; they would probably screen themselves behind the assertion that men do not regard themselves as privately responsible for their participation in the acts of a public body; and many more such assurances, to which no other reply can ever be made than the old "*Honisoit.*"

It may be of more avail to ask the few who entertain such suspicions, to compare the anticipated evils of this proposed plan with the positive and insuperable evils of the present. Do they now, when it is fairly presumable that no partiality to hospital schools is shown, and when it has even been unsuspected that the scale is made to preponderate on the opposite side—do they now obtain a satisfactory supply? Are they now able even to procure the requisite subjects for their lectures, or to fulfil the compact into which they entered with their pupils when they received their money? We can positively answer for them—No: there is not one teacher of anatomy in the metropolis whose pupils have not just ground for complaint that they are not receiving the advantages for which their money was paid, and which they were virtually implied, if not verbally promised.

The present scheme is positively bad: we can scarcely imagine it to be worse: to this there is no dissentient, and all will readily agree that there is no hope of amendment while things continue as they are. Neither is there any prospect of remedy in slight modifications of it: the opponents of the plan above proposed may advance suspicions against it, but they do not pretend to put forward any suggestions for the improve-

ment of the present: they can at best only say, they would

—— "rather bear those ills they have  
Than fly to others that they know not of."

They are in a strait between fears and feelings.

Let us compare the present and the anticipated evils. The whole source of the present annoyance is an insufficient supply of subjects, and the insufficiency is felt especially by those schools which are not attached to hospitals. It may be assumed, therefore, and we believe (for we would believe nothing to the contrary, without evidence) that there is perfect impartiality in the distribution of those bodies that are consigned to the Inspector. With this impartiality, the private schools are badly, so very badly supplied, that their work is almost at a stand-still: they cannot compete with the schools to which, being attached to hospitals, a certain, though still a very insufficient number of bodies, *must* come. This inequality of supply, too, takes place in the very face of the pretence that the Inspector distributes the bodies according to the number of pupils in each school; in the very face of the long and annoying process which was ordained last year, of registering the name, place of birth, and residence of every medical student in the metropolis. And in the present plan such an inequality must exist: the Governors of hospitals have neither the will nor the right to let the body of any patient to whom they have proffered their charitable assistance, go off their premises except to their burial-ground: if an hospital patient is friendless, the guardians of the place in which he dies—the trustees for the funds that were expended for his benefit while living—must be his friends after death; they are bound to secure him the decent burial of his remains, and they can do this only by preventing his body from passing into the hands of any but those

whom they deem trustworthy, and over whose interests they have a constant and immediate control. So long, therefore, as the supply from common and public sources is small, the hospital-schools *must* have a greater supply than others; and this latter evil, the chief of those dreaded from the adoption of the new plan of giving to the College of Surgeons the office of procuring subjects, now exists in full force.

Whatever system of distribution therefore is adopted, and however anxious the Inspector may be to give the private schools advantages equal to those of the hospitals, it is clear that nothing can be done for them so long as the public supply is thus limited: the Inspector can only give them in proportion to his own receipts. The only chance that the private teachers have of placing themselves on a level with their more fortunate opponents, is to adopt any measure by which a supply might be obtained so plentiful that there should be no place for quarrelling. If we may be allowed the expression, there will never be a sufficiency of subjects till there is a superfluity;—there will never be an equality of distribution, or contentment, or fair play, till all obtain as many as they want or can fairly use. Such a supply (we say it from some experience) London is fully capable of yielding, and ought to be made to afford; but such a supply, for reasons which it would be annoying and unnecessary to repeat, never will be obtained so long as the present system continues.

The plan by which the supply may be improved is sufficiently simple and plain. There may still be a Government Inspector, (and in the discharge of this part of his functions none can be less offensive to the schools than the present,) whose duty it should be merely to see all the provisions of the Act properly complied with;—to see to the regular and decent reception, and

the burial within the allotted term, of all the subjects that are dissected. He should have, in short, only those duties to which he is appointed by Government, under the express enactments of the Anatomy Bill, and thus neither he nor any of his friends could have just cause of complaint. But with respect to his superadded office of obtaining, or rather of not obtaining, a supply of subjects, that should be entirely removed: without mentioning one personal objection, there are fifty reasons why a servant of the Government is unlikely to succeed in such an office; he is himself not sufficiently interested in the cause, and to those with whom he has to deal, nothing can be more offensive than the tone of authority which any emissary from Government can scarcely avoid assuming.

The obtaining of subjects should be placed in the hands of those who are personally interested in getting them; and if the Anatomical Teachers could be brought to agree, they would themselves be better fitted for the work than any whom they can request or depute to undertake it for them; but the winds may as well be expected to blow all in the same direction, as such conflicting interests to be made to coincide in a common work. If any thing be less promising of success than the present plan, it is that which some have imagined might be effected by a union of teachers; in fact, the present mismanagement is the offspring of the failure of such a scheme attempted at the first introduction of the Bill.

As far, therefore, as we can see, the only means left is to place the matter in the hands of the College of Surgeons, or some similar public board, who would engage to obtain an adequate supply to be fairly distributed among the schools. We need not point out how intimately the College, in these days of competition, is interested in sustaining their

reputation. Nor would they, we imagine, omit the necessary provision of rewarding their agents according to the success of their work, paying them a certain sum per body—a plan which, were it adopted even now, would have, we are inclined to think, a marvellous influence in stimulating some persons' energies, and which can alone secure any work of the kind to be well done.

If we must again recur to the suspicions that partiality would be shewn by the Council to their own friends, what, we would ask, is the objection on this score that might not be urged with equal justice now? What are the present protections against partiality? The Inspector's personal character; and is not that of each member of the College quite as respectable? The Inspector's books, which are open to public examination; and would not those of the College be open too, and be kept with at least as much accuracy and fairness? And further, if a cause of complaint of any kind did arise, from whom is redress most easy to be obtained, and which is most easy of access and most responsible? Why the College, ten times over. There is not an anatomical teacher who does not know that the present Inspector is virtually totally irresponsible; that he can set at nought all their complaints, and in his snug safe birth can laugh at all their distresses, so long as his friends remain in power; and that he could do this though all the faults of which the teachers accuse him were distinctly proved against him. He is as fixed as his own principle of inertia, and his faults are irremediable. The College of Surgeons, on the other hand, has shewn itself far more tender of its reputation, and could not safely expose itself to charges which he can bear with impunity; so that admitting (though this must be for mere argument's sake),

that in every other respect they and the Inspector were equally ill adapted to the work, his irresponsibility and want of personal interest in success would be quite sufficient to prove the latter least fit for it.

We shall here leave the subject for the present, in the hope that this will be the last time we shall need to consider the matter, except to congratulate our readers on some improvement.

#### A PEERAGE REFUSED.

AT the late creation of peers in France, the name of M. Double was decided on as that of one fit to be raised to the dignity in question. The offer was then made to him, on condition that he should renounce the exercise of his profession! To this proposal M. Double refused to consent, not choosing to purchase the honour at so dear a price; and we cannot but remark, that the spirit evinced by the French government on this occasion is very different from that which actuated Napoleon, when he constituted Cabanis, Berthollet, and Fourcroy, peers of the empire.

#### BÖHM ON THE MORBID CHANGES IN CHOLERA.

THE following analysis of Dr. Böhm's important investigations in cholera, is given by Henle, in his *Retrospect of the Progress of Pathology*:—

In the contents of the intestines of cholera patients, Böhm has discovered the debris of the epithelium of the mucous membrane of the digestive canal; and he thence refers the phenomena of the disease to a morbidly accelerated process of desquamation from the membrane, which he has accurately traced through its several stages. The affection of the internal surface of the digestive canal is not equal in its several parts: the stomach suffers little, and the large intestines least of all; in the small intestine, which is for the most part attacked throughout its whole length, the desquamation is the greater the nearer the part is to the cæcal extremity, at

which it appears to commence, or at least to proceed most rapidly. At the upper part of the intestines one usually sees, even with the naked eye, limited and isolated portions, which are distinguished by a whitish colour, and a looser velvety aspect: on these the first step towards the separation of the cuticle is observable. The villi appear swollen and elongated, and the epithelium seems split into its elementary parts; the cells which I (Henle) have described as *cylindri mucosi*. Here and there greater cracks soon form; and the pieces thus separated, consisting of a greater or less number of cylinders, come off in fragments; the villi are thus exposed, and they are seen to be only here and there covered by a remnant of epithelium. At last the villi are completely uncovered, and they appear beset with a number of dark points, which Böhm regards as fossule, in which the apices of the cylinders of epithelium were fixed. (I think they are rather the nuclei of cells, which, perhaps, are now seen in the proper tissue of the mucous membrane, in unusual abundance, for the reproduction of the epithelium). But besides this immediate exfoliation, the desquamation takes place also in larger pieces, so that the epithelial coverings of the villi separate from the mucous membrane, but remaining connected together are swollen into hollow sacculi. By passing a fine instrument lightly over the surface of the membrane when in this state, one can remove the upper halves of the sheaths of epithelium, which lie only loosely like cupolas on the villi, and then the villi appear projecting out of the lower portions of their epithelial sheaths, as if out of wide tubes. The same process which may be thus observed on the villi, occurs also in their interstices, and whole lamellæ of the epithelium may be separated, which present on one side a series of prolongations in the form of villi, and on the other surface the openings which lead into those prolongations.

After the separation of the cuticle, and when a raw surface remains, the destruction goes on in the very substance of the mucous membrane. The villi become thinner and weaker; by a kind of maceration their swollen free extremities split up, and assume a fibrous appearance, by the increase of which they are gradually cleft to their bases. The intestine thus affected in irregularly scattered spots, looks like an old hide from which the hair is in part worn off. The extreme degree of destruction is found at the end of the ileum, where the Peyerian glands perish, and the mucous membrane is converted into a cracked and broken-up surface.

But the whole process is effected with such rapidity, that patients who in the morning complained of at most an uneasy moving of the intestines, and who die at noon, already present at their post mortem examination a considerable destruction of the mucous membrane.

It is the fragments of the epithelium which, mixed with the effused fluids, form the contents of the intestines. If the latter remain for a certain time at rest in a glass, their microscopic constituents will sink to the bottom. The contents of the intestines appear milky, when the quantity of the secretion is considerable in proportion to that of the elements of the epithelium, and the latter are very minutely divided; they are pus-like or creamy when, on the contrary, the quantity of fluid is small in proportion to that of their solid constituents; flocculent when the epithelium cells are still connected in considerable masses; rice-water-like when similar flocculi float in smaller numbers in a turbid fluid; gruel-like when larger portions of epithelium, some of a white and others of a greyish green colour, are mixed with one another, and connected by a scanty secretion, into a mass of a pulpy consistence. The contents are adherent when the cuticle has not yet completely separated. This adhering layer has been taken for effused plastic lymph; but that it is not so, is proved by its microscopic examination.

Mucous matter within the intestines is rare; it is produced when the elements of the epithelium are dissolved in the intestines, and the more mucous the substance, the less evident are the outlines of the epithelium cylinders.

In the fluid of the large intestines the cuticle of the small intestines appears to be dissolved, for from the colon downwards scarcely any of its fragments can be formed, and in the patient's evacuations they are still more rare. The bilious colour of the contents of the intestines depends in like manner chiefly on the particles of the epithelium, which become tinged with bile. The secretion of bile is suspended at the beginning of the disease, but it is only in the most acute cases that death ensues before it has again commenced; most of those who are attacked die at a time when the bile has again diffused itself over more or less of the surface of the small intestines. If death ensues after a nervous reaction, or by debility, then the bile usually appears in a great excess. The hepatic ducts are for the most part empty and dry; but when compressed a small quantity of clear yellow substance proceeds from them, which

in like manner consists chiefly of their epithelial covering.

Böhm hence concludes that the liver is always affected, and that it takes part in the pathological action of the intestines. But at such a time after death as the examination of the bodies must take place, the epithelium may be pressed out of all the gland-ducts with but slight force, and this fact, therefore, does not appear to me sufficient to prove disease of the liver. That the bile ducts should be dry, while the intestines abound with watery effusion, is rather an argument for the two organs being in opposite conditions, and the arrest of the secretion of bile, like that of all the other watery secretions, can depend only on the blood losing the chief part of its serum by the oozing of the latter into the intestine.

Vomiting of bile is rare, and a favourable symptom. More commonly there is found in the matter that is vomited a dark almost black slimy substance, which, in the post-mortem examinations, is also found firmly adhering to the wrinkles of the stomach. Böhm considers that this is bilious matter, peculiarly altered by the disease, and, perhaps, occasionally secreted by the stomach instead of the liver. It is turned reddish brown by nitric acid, and in caustic potash dissolves into a green fluid, just like bile; but so does the colouring matter of blood. Blood also, when it comes in contact with the gastric juice, is converted into a black tar-like substance, and consequently when blood is poured into the digestive canal generally, it will have the blackish appearance, such as Böhm describes, only in the stomach. I have, therefore, no doubt that this is blood, which is effused in consequence of rupture of the vessels or destruction of the mucous membrane on the surface of the stomach, more especially as blood is effused in cholera in other forms and under various circumstances.

The intestinal evacuations of cholera patients are in general transparent, and only rarely, in the first stages, somewhat coloured with bile. They are distinguished by white and often very large flocculi, which must not be confounded with those which the intestines contain after death. The evacuated flocculi consist of very fine and long semi-transparent threads, of an elastic consistence; they sometimes enclose mechanically small crystals, and it is therefore probable that they are formed by the coagulation of some substance. From his description and drawings of them it seems to me in the highest degree probable that these flocculi are coagula of fibrin; and it may be fairly supposed that they form immediately from the effused serum.

A similar creamy matter to that which is found in the intestine occurs also in the pelvis of the kidney, the ureters, and the bladder, and is evacuated with the urine, when on returning health its secretion is restored. This also consists of fragments of the epithelium, from different parts of the urinary passages.

Coincidentally with the epithelial covering of the villi, that of the Lieberkuhnian glands also exfoliates; it protrudes from them in the form of little tubules, and fills up the interspaces between the villi in the surface of the intestine.

The alterations of the solitary and Peyerian glands in cholera, result from two different processes, of which the first has its seat in the surface of the mucous membrane, and the second in the cellular tissue below it. The mucous surface of the glands is destroyed, the little capsules ulcerate out, open, and disappear to their extreme border. Their cavities thus form little fossulae, and the surface becomes net-like. At the same time the tissue beneath them is filled by a white plastic exudation, and is thus swollen; but this change never reaches to such an extent in cholera as in typhus abdominalis. A third form of alteration in the Peyerian glands consists in the surface over them becoming covered with a number of tortuous folds, lying close by one another; in general, however, this occurs only in young subjects, and it is explicable by the aspect of the Peyerian glands in the child. The folds, which are then normal, become at a later period again visible by the thickening and swelling of the surface. The Brunnerian glands are also elevated, by the effusion into the cellular tissue beneath them, so that they sometimes seem as if they were set on stems, projecting far beyond the level of the mucous membrane.

Böhm has abstained from all conjectures on the nature of the process which he has thus accurately followed in all its phenomena. But I find that the expression he employs of "an excessive desquamation" gives rise to misunderstanding. One might certainly, among the morbid processes on the skin, call pityriasis an excessive desquamation, because in it an excess of cuticle is formed, and an excess cast off; but we should not call by that name the separation of the cuticle from the cutis by a blister, so as to leave a raw surface behind. But the process by which the epithelium of the intestines is removed has the greatest analogy to the formation of vesications, and Böhm has himself, in many places, compared the one to the other. The cause of desquamation is a mechanical and passive separation of the cuticle by the exudation, and the exuda-

tion is the essential part of the disease. This may be produced in two ways; either by a primary general alteration of the blood, by which it becomes thinner; or by a local stagnation and change of it by a process which we name inflammation. The first is improbable, because the process is limited to the intestinal canal, although the inner surface of the lungs, and of many other organs, is not less delicately formed than it. For the second view, the symptoms of the disease and other morbid appearances, which Böhm found after death, are all favourable; as, for instance, the injection of the vessels which is constantly coincident with the desquamation, the tinging of the whole substance of the villi with blood, the presence of fibrinous coagula in the effused fluid, and the exudation of plastic lymph on the outer surface of the mucous membrane, in the region of the Brunnerian and Peyerian glands. All the secondary symptoms of cholera are explained by the great loss of serum, which takes place so rapidly from the walls of the intestines, from the alteration of the blood thereby produced, and from the extended affection of the nerves of the internal surfaces. These circumstances do not act differently from a burn, which is attended with blisters over the whole surface of the body. — *Müller's Archiv.*, Hft. iv. 1839, p. xli.

### ST. THOMAS'S HOSPITAL.

WE were mistaken in supposing that the resignation of Dr. Roots, which we alluded to last week, had any thing to do with his health, which, we are happy to learn, has long been quite re-established. His retirement, we are informed, was caused solely by the press of his private engagements.

### DEATH OF DR. HAMILTON.

DR. HAMILTON, whose illness we announced last week, died on the 14th instant, at his house in St. Andrew's Square, Edinburgh. He had been for a great number of years Professor of Midwifery, and was the last of a generation now completely gone by. He was a very animated lecturer, and, we believe, an energetic practitioner, retaining to the last the utmost vivacity in the maintenance of his opinions, as some papers published only last year, in the pages of this journal, will sufficiently demonstrate.

We have already heard of various candidates, both in Edinburgh and London, who are anxious to succeed him.

### APOTHECARIES' HALL.

#### LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, Oct. 31, 1839.

William Smith, Horncastle, Lincolnshire.—John Onon, Birmingham.—R. W. Foster, Tolmorden, near Halifax, Yorkshire.—H. A. P. Robertson, Bristol.—John Kitching, Kingston upon Hull.—W. G. Goodridge, Shriminster Newton.—Richard Taylor, Wigan, Lancashire.—Edward Rayner, Lincoln.—Charles Jones.—J. G. Porter.

### WEEKLY ACCOUNT OF BURIALS.

From BILLS OF MORTALITY, Nov. 19, 1839.

## LECTURES

ON THE

### PRINCIPLES AND PRACTICE OF SURGERY.

*Delivered at the Westminster Hospital School,*

BY BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

#### SUPPURATION.

**Pus, continued.**—*Can it be distinguished from mucus?—from tuberculous matter?—Summary of its qualities—Origin of fibrin globule?*

**ABSCESS.**—*Definition of—Formation—Parietes—Functions of parietes—Elaboration of pus?—Progress—Acute abscess—Characters—Chronic abscesses of various kinds—Characters.*

*Diagnostically considered.*—Up to the present moment all attempts to ascertain the nature of pus have been unsuccessful; all attempts to distinguish mucus from pus have been equally unsuccessful. The old test was water, in which mucus was believed to float, pus to sink; and really this test does not merit all the contempt with which it has been regarded in modern times. In water holding saline substances in solution the experiment is better; Hippocrates was aware of this, and therefore ordered patients to spit into sea water. Darwin proposed four distinctive characters: first, he says sulphuric acid dissolves pus and mucus; the latter is condensed into large flakes, which float in the solution; the former is precipitated in the form of a sediment. Other observers are not agreed on this first point. Nitric acid equally dissolves pus and mucus; water precipitates the first solution, and makes the second turbid; but as nitric acid dissolves neither pus nor mucus, the experiment is worthless. Again, says he,

mucus and pus are dissolved in caustic potash, but the latter alone is precipitated: this experiment is not confirmed. At last he says, corrosive sublimate coagulates only mucus—a fact *à priori* impossible, since pus contains albumen, which is readily precipitated by sublimate. Bruggmann eulogised the means proposed by Darwin, and added another. “Pus,” says he, “before entering into putrefaction, becomes acid; this is not the case with mucus, which exhales no particular odour.” But this is an insufficient distinction, for most substances, before entering into putrid fermentation, give out acetic acid (Weber). Smell is not a distinctive sign; good pus is, like mucus, without odour. That pus is alkaline so long as it remains in contact with an ulcer—that it afterwards becomes neuter, and later acid—is stated by Gueterbock. This sign cannot, however, be regarded as distinctive, since many substances, before undergoing putrid fermentation, give out acetic acid. Hunter first perceived that pus coagulates by the addition of a concentrated solution of muriate of ammonia, which, according to him, distinguishes it from many other animal fluids. It is true that this gelatinous appearance is so produced; but Pearson justly remarks, that it is not a coagulation, but a thickening produced by concentrated saline substances, which absorb water from pus. Diluted saline solutions do not produce similar results; besides, heat precipitates albumen from this mixture. Hydrochlorate of ammonia is without action upon filtered pus, and upon the globules alone. It therefore follows that this phenomenon is not peculiar to the serosity of pus, as Hunter believed. Grasmeyer recommended that the fluid to be examined should be mixed with tepid water; to this a certain quantity of a saturated solution of carbonate of potash should be added. Pus so treated changes soon, which is not the case with

mucus, into a transparent, gelatinous, viscid mass; the transformation is as much more rapid as the pus is healthier. But then Gueterbock says he has obtained the same results from pure mucus secreted in the fauces, and mixed with a very little water. In fact, the gelatinous mass is probably produced by the coverings of the pus and mucus globules, and may thus equally form in mucus; this means, therefore, is insufficient. Gruithuisen proposed another test: if you pour pus and mucus into distilled water, and after putting both fluids into vessels closed with thin silk, expose them to light, and to a temperature of from 97 to 106 Fahrenheit, infusoria will be developed in each, but their characters will differ. Those of mucus are a hundred times larger than those of pus, swim very rapidly, while those of pus, lenticular in form, move very slowly. If, adds he, you pour water into a mucopurulent fluid, you will see neither the infusoria of mucus nor pus, but the animals which resemble those of mucus and pus may be regarded as a mixed product. This test will not hold; Ehrenberg has demonstrated that the animalcula of these infusions have nothing constant about them; that the infusion of the same substance sometimes produces one animalcule, sometimes another. Preuss recommended as a test, to burn the fluid, and treat the ashes with hydrochloric acid, and to seek for iron by means of the ferrocyanate of potash; if its presence be established, it is pus or tuberculous matter; if not, it is pure mucus. This is a doubtful experiment, because the quantity of iron in pus is so small, that the ferrocyanate of potash may not indicate it. Donne proposed a new test, to shew when pus is mixed with blood, even in small proportion. Pure blood, says he, is made transparent by the addition of caustic ammonia, which dissolves its globules; but if it contain the smallest quantity of pus, it is changed into a filamentous mass; and if the quantity of pus be larger, it becomes almost gelatiniform. He afterwards changed this opinion, because pure blood becomes gelatiniform by admixture with caustic ammonia. He gives another mode of detecting pus in blood. Blood, says he, only presents its own proper globules; if we discover with the microscope larger globules, we must add liquor ammoniæ, which does not dissolve the pus globule. It seems to be true that globules of blood are soluble, and globules of pus insoluble in this fluid; it may therefore be held to be a test of pus in the blood, but the test recommended by Gueterbock and Galliver is more simple; water dissolves the covering of the blood globule, and does not exercise the same

action on the pus globule. Gueterbock's summary of the subject I will give textually:—"I shall give in a few words the differences I have found between pus and mucus, and the means which I have found most convenient in distinguishing them. Pure mucus, secreted by the nasal fossæ, larynx, bronchial tubes, and rectum, has never presented albumen, except when these membranes were much irritated. I am convinced that mucus contains pyine, but I have not detected in it osmazome; neither have I been able to extract from it fatty matter." Here, then, are differences between pus and mucus. But then, as in certain cases it may secrete pus mixed with albumen, the fatty matter seems to be the character most proper to distinguish pus from mucus. Michael says that pus containing much fatty matter burns with a bright flame like resinous substances, whilst mucus, when it burns, only disengages some inflammable gas which burns. Gueterbock says this plan has succeeded, in his experience, when the proportion of pus was extremely small.

It is not easy to distinguish purulent from tuberculous matter; if tubercles be taken from the glands of the neck or the bronchia, Preuss says, and this is confirmed by Gueterbock, that they will be found to contain no albumen; heat, however, will indicate the existence of a little; if the matter be mixed with water, and filtered, a fluid is obtained, which is rendered turbid by acetic acid, as well as by a solution of alum; soon a deposit is formed insoluble in an excess of these reagents; instead, therefore, of containing caseous matter, he thinks they contain pyine; he did not recognise osmazome, but instead of it the substance described by Preuss as phymatine, which, soluble in alcohol and water, is not precipitated by a decoction of galls, but which, like osmazome, is precipitated by the acetate of lead, and is not rendered turbid by sulphate of copper. Tubercles, therefore, differ from pus, by the proportion of albumen, by the presence of phymatine by which osmazome is replaced, by cholesterine which is not found in pus; still in the pus of scrofula all these substances are found; the difficulty of distinction is therefore very great.

In conclusion, pus is in appearance an unctuous homogeneous fluid, heavier than water, of a whitish yellow colour, of varying consistence; though commonly like that of liquid honey, of a sweetish taste; when warm of a mawkish smell, which is dissipated by cooling. When examined by the microscope it is found to contain an immense number of globules of unequal volume, and a large number of granules or molecules, which seem to be the nuclei of globules. Jordan found it composed

of water, fibrin, mucus, albumen, chloride of soda, and phosphate of lime; Gueterbock, water, adipose matter, soluble only in boiling alcohol; adipose matter and osmazome, soluble in cold alcohol; substances insoluble in boiling or cold alcohol (albumen, pyine, globules and granules of pus), and saline matter. Cruikshank detected iron; this had already been done by Salmuth and Schwilgne; Pearson described four varieties, the creamy, the curdy, the serous, and the slimy pus. All these species are susceptible of coagulation at a temperature of 165° Fahrenheit. Pus of chronic inflammation is more liquid and less homogeneous, and separates into two parts more readily than when it is creamy. Pus of caries contains phosphate and chloride of lime; that of serofulous ulcers, soda and chloride of soda; that of gouty ulcers, carbonate, phosphate, and urate of lime. The serous pus of ulcers contains more salt and albumen in solution; that of hospital gangrene, according to Cruikshank, contains no other elements than that of wounds. Again, there is no apparent physical difference between virulent and healthy pus; that of syphilitic ulcers is perfectly similar to laudable pus; that of variola and vaccinia are similar; this shews that the deleterious qualities of these fluids escape our means of investigation, and reside more in a dynamic power than in a certain combination of the elementary particles of which they are composed.

You must not, however, understand that these changes in smell, taste, or other physical or chemical properties, affect the globule or the granule; we see no definite change in them under these circumstances; we can wash away all their impurities, and shew them unchanged.

*Fibrin Globule.*—To what the white "lymph" or "fibrin" globule of the blood owes its existence, is a matter in dispute we believe to fibrin; that is, we believe the granules to be fibrinous, and while the blood is circulating to be held in solution in its serum; we believe, further, that this globule is not formed until the serum has escaped from the vessel; that once escaped, under one train of circumstances, it may constitute a component part of pus, under another of mucus, under another of saliva, under another of urine. Vogel, who admits the existence of these bodies, explains their origin in another way; he believes that the cells of the epithelium of vessels are constantly transformed and thrown off; this also is the opinion of Henle. These cells, which in their natural condition are, say they, provided with a central nucleus, as shewn in fig. 10, contract, become granulated at their surface, and in the end present only their original

nucleus or granule. Vogel goes further, and attempts to shew in the presence of the particle of epithelium a characteristic sign of mucus. That such an epithelium is constantly thrown off and mixed with the different fluids is no doubt true; if we examine mucus we usually see these debris, varying in form upon different organs; but if these debris constitute the pus globule, how is it we never find them in the blood until it has been a short time under the microscope? If it be answered that they may be dissolved in the serum, I have nothing more to say than that it is an hypothesis unsupported by any physical evidence.

#### ABSCESS.

*Abscess.*—So formed, pus is either circumscribed, so as to constitute abscess, or it is diffused, no adhesive inflammation occurring to limit it. In the latter case it is termed diffuse phlegmon, or erysipelas phlegmonodes, and the pus is diffused through the integuments far and near: these tissues are thinned, broken down, and often sloughy; the interstices of muscles are invaded, and often when the integuments slough away the muscles are as completely dissected as if a scalpel had been used for the purpose; no pyogenic membrane, no limits to the abscess, can be discovered. The consideration of this condition we shall reserve until we treat of erysipelas; in this place we shall enter upon the subject of abscess.

Whether the term be derived from the verb *abscedere*, because pus separates parts which were before contiguous, or because it is separated from the blood, is unimportant; we apply the term to collections of pus in a newly formed cavity.

As abscesses can only occur in such situations as will admit of pus collecting, there are certain tissues and organs in which they cannot happen: in the fibrous, fibro-cartilaginous, serous and synovial membranes, they are not seen; pus may be secreted upon a serous surface; the surrounding inflammation may be less intense, and adhesion may take place between the opposed surfaces; the pus may thus be imprisoned, and a purulent collection or abscess may be thus formed, but not in the substance of this tissue. Purulent secretion very frequently takes place on mucous surfaces; but then it is easily carried off. There are, however, a few situations in mucous surfaces where pus may be collected; the nasal sinuses, the cavity of the tympanum, the lacrymal sac. Pus may be effused into the cavity of a vessel, an artery; but it does not constitute an abscess, but in veins the collections are sometimes considerable. But of all the tissues of the body, the cellular is that for which purulent

collections appear to manifest the strongest predilections, so strong as to induce some pathologists to maintain that it was the exclusive seat of abscess; it is certainly true that they are found in this tissue much more frequently than in all others put together; but in all situations this tissue does not evince the same disposition. Hunter was clearly right in the opinion that the farther removed from the surface of the body, the less was the chance of abscess; whether this be because the deep-seated tissues are less exposed to those accidents by which suppuration is brought about, it is difficult to determine, though I incline to the opinion that, under similar circumstances, suppuration is less easily established in the deep-seated than in the superficial tissue. With respect to hollow organs, abscesses may be developed in the walls of the pharynx, the œsophagus and the stomach, the intestines and the bladder; but these are unquestionably abscesses of the cellular tissue entering into the composition of these several organs. In the glandular secretory organs abscesses may form: the lachrymal gland, and pharynx, however, seem to be exempt. The brain and spinal cord are not exempt; but abscesses in these organs are usually chronic, usually succeeding to concussion, contusion, or other injury.

We have endeavoured to support the opinion that pus is never formed in the absence of inflammation, and consequently, abscesses cannot be developed without it.

*Pyogenic membrane.*—Whenever a collection of pus is found, if it be not very recently formed, a particular tissue separates the purulent matter from the neighbouring tissues. To this tissue the term false membrane of abscess and pyogenic tissue has been applied. But the constancy of its existence is not so great as was believed by Delpech and others. It is true the greater number of persons who have studied this subject have regarded this membrane as the result of an action subsequent to suppuration; a work by which nature sets up a barrier against the diffusion of purulent fluid. Whether or not, in all cases of abscess, rapidly formed, the pyogenic tissue exists, it may be difficult to determine. Delpech and Home believed it to be pre-existent. I have already given my reasons for thinking that frequently it is not so; certain it is that there are many cases of abscesses formed in a few days, where no distinct mucous-like membrane can be demonstrated. Where an abscess succeeds to inflammation, of the ordinary uncomplicated character, "*inflammatio genuina*," as it has been termed, it is true there is an effusion into the surrounding tissue of a serous fluid holding lymph or fibrino-albuminous matter in solution; once out

of the circulation this matter concretes or coagulates; the tissue in which it is extravasated loses its permeability, and thus a barrier being formed around where the pus is poured out, there it remains. It is the barrier then which constitutes the great difference between diffused and circumscribed collections of pus. Why, in the one case, this barrier is absent, and in the other present, I cannot tell. I apprehend it depends more upon the nature than on the seat or the intensity of the inflammatory action. The whole of the symptoms which accompany diffuse suppuration, the circumstances under which it is commonly seen, the inoculation of a putrid principle during dissection, are sufficient to shew that there are states of the system in which nature seems to have no power to give to the products of inflammation that plasticity by which a limit is placed to the diffusion of the evil through surrounding parts.

I believe that the walls of a very acute and very quickly developed abscess have no other covering than that which is furnished by the infiltration of the adjoining tissues, by means of coagulating lymph; there is no true membrane capable of isolation from adjoining parts. It must not, however, be supposed that the barrier which we are describing does not readily assume the characters of a living tissue; all I wish to convey is, that it has none of the characters of a pyogenic membrane. Gradually, however, the tumefaction subsides, as the abscess approaches maturity, and the membrane acquires a pyogenic character, and becomes insensible of separation by dissection; but this rarely happens when the progress is very rapid.

We have now considered abscess, from the moment suppuration is declared, to that when an accidental membrane is developed to surround it. When this new organ is fairly formed it acquires the power of secreting and absorbing. But I do not hold that the following reasons are sufficient evidence of these qualities: "The sojourn of a considerable quantity of an animal fluid, in the midst of our tissues, at a temperature so favourable to decomposition, without alteration, can only be explained by assuming that it is constantly renewed." It is commonly believed that the pyogenic membrane is the seat of a continual exhalation and absorption, by means of which this fluid is renewed. To demonstrate this double action is not easy. If we look at the extreme rapidity with which, after evacuation, large chronic abscesses sometimes refill, we must believe the action of exhalation to be very energetically performed. Again, in certain abscesses, scrofulous for instance, we may see the integuments over a purulent col-

lection so thinned that the cuticle alone seems to restrain it; and yet that fluid shall be completely absorbed. If those two actions, in ordinary cases, exist at the same time, one is usually more energetic than the other; the exhalant action predominates, and the abscess enlarges; no matter how dense the tissue in which it is seated. Morgagni describes a chronic abscess of the brain, which dilated the cranium and pushed out the frontal sinuses.

*Mode of extension.*—How the extension of abscess has place is the next question; to admit of this, the barrier must either be broken down and destroyed, or extended. The memoir of David, which was crowned by the Ancient Academy of Surgery, was based on the assumption that pus possessed a solvent action, and that in this way the "callosities," as he termed the parietes, were dissolved; the extension depending upon the dissolution of the parietes. In our opinion, that portion of the walls in contact with the pus does not undergo this destruction, but yields to the extension which is made; whilst the same pressure causes the absorption of the outer part of the walls, and the irritation thus developed occasions an extravasation of lymph around the circumference; but a certain distance removed from it; in this way, as the pressure from within increases, the sac extends. Some men say there is incontestible evidence of breaking down and destruction in the sloughy cellular tissue, seen in diffuse suppuration; that is true, as applied to that particular form, but not to the circumscribed form. When the abscess is subacute or chronic in its form, the development of the internal or pyogenic membrane is more distinct; it is then soft, velvety, in colour reddish, greyish, slaty, or even blackish; sometimes not unlike in appearance to the mucous coat of the stomach. Under this membrane is another, denser, less organized, whiter, and of variable thickness.

*Direction.*—Usually, in enlarging, progress is made in the direction where the resistance is least marked, but almost always tending towards the surface. This point was well considered by Hunter, and afterwards by Thomson. It is interesting to inquire whether it really be the lesser resistance offered which occasions the tendency to the surface of the body in such cases. Hunter clearly believed that the cause was not so mechanical; that it was a provision of nature, for the protection of the individual; a power like that which, under almost every circumstance, directs the plumule towards the atmosphere. As a poof of this tendency, he refers to cases where a bullet has formed a long subcutaneous canal with two cutaneous

orifices, and has carried with it midway some foreign body. The abscess which is occasioned by this foreign body is not evacuated at either orifice, but passes directly towards the surface of the body. Unquestionably abscesses much more frequently present themselves at the cutaneous than the other surfaces of the body; yet they may open elsewhere; a strong aponeurosis may interrupt their progress towards the skin, and they then take a different course. An abscess of the liver may open into the stomach or the colon; the latter is a fortunate termination; so is the opening of an abscess of the iliac fossa into the cæcum. An abscess situated externally to a serous cavity very rarely opens into it. To that phenomenon by which nature directs these collections towards the surface, the term progressive absorption was applied by Hunter. To the means which nature employs to rid herself of these collections, the term ulcerative absorption has been applied. There are certain circumstances which may be urged in support of the opinion that it is not by simple distension alone that the work is effected: thus even although we may make one or more punctures, nature will proceed with her work, and a spontaneous opening may be the consequence. If an abscess be formed in the lung or in one of the abdominal viscera, the tendency is still towards the cutaneous surface; if it be in a lung, the pleura becomes inflamed, lymph is poured out between the pulmonic and costal pleura, and the pus passes on towards the surface instead of being poured out into the pleural cavity; but it is not always so.

Once opened with a cutting instrument, it may happen that the opening is enlarged by ulceration; but this more frequently happens when the opening is spontaneous and the integuments much thinned. If it be well-conditioned, the parietes undergo change, and granulations are developed, the cavity contracts, and ultimately the sides adhere. I believe, however, that occasionally it happens that the cavity is obliterated without granulations, for we sometimes see cases in which they are closed within forty-eight hours. But these cases are not the most frequent: the integument is thinned, the cellular tissue is destroyed, and the patient is emaciated. This is especially the case in the axilla and about the rectum. The pus which succeeds to acute inflammation in a part well provided with cellular and adipose matter, is healthy—laudable. Is it always so, or does it pass through certain stages of elaboration? That pus undergoes changes in its physical characters is evident: the pus of an abscess prematurely opened is

very different from that of one which has attained maturity. Yet these changes do not seem to affect the globule, but only the fluid part. Thompson maintained that the term maturity, as applied to abscess, was improper; that the fluid underwent no metamorphosis; that it was only more or less "collection." If we admit this identity of pus at different periods of the existence of abscess, we must, I apprehend, also admit a similar identity, whatever the nature or the intensity of inflammation, or the composition of the tissue in which it is developed. This, I think, we cannot do, unless we admit that pus and pus globules are synonymous terms. I have already stated the reasons why this position cannot be accepted. "The pus of muscular tissues is yellowish grey; that of the liver is often of a brownish-red." The pus of chronic abscesses—lumbar, for instance,—is a thin, ill elaborated fluid, greatly mixed with other substances. Where abscesses are consequent upon, or connected with, diseased bone, the pus is usually greyish, with fibro-athous flocculi floating in it; sometimes small clots of blood and portions of phosphate of lime. Its odour is extremely nauseous, and this is usually enough to distinguish its origin and nature: but this odour is hardly ever developed until some days after the tumor is opened, and air has been admitted. That the globules in these several cases are identical, I do not doubt: that of the liver is mixed with bilious matter, and with the broken down hepatic tissues.

*Acute abscess.*—The ordinary phlegmonous abscess may be developed under the influence of any cause capable of exciting inflammatory action: it may be presented at the irritated point or at a distance. For instance, there may be a slight excoriation upon the great toe, the lymphatics or veins may be irritated, and red lines may mark their course up to the groin, where acute inflammatory action may be developed. An irritation in the urethra may be rapidly transmitted to the testicles. They may be developed under the influence of general irritation, cutaneous abscesses in fevers, those of small-pox, and certain other diseases. It is singular that a large proportion of cutaneous abscesses are developed about the neck and ears. There are yet others developed under peculiar circumstances; an organ is inflamed—a gland, for instance; it communicates the irritation to the surrounding cellular tissue, which becomes the seat of abscess, while the organ itself escapes. This is not uncommon in muscular or fibrous structures affected with rheumatism—those of the cheek, in persons suffering from violent toothache. Abscesses of an acute character are often developed

under the irritation occasioned by the presence of a foreign body, whether solid or fluid: the latter, from their susceptibility to pass through greater spaces, usually excite more intense action. They may be developed within the body, spiculae of bone, or infiltrated urine, or they may be introduced from without; port wine injected into the cellular tissue of the scrotum, instead of the tunica vaginalis; it may be produced by the irritation of a large quantity of extravasated blood. These collections, whether a consequence of the bursting of an aneurismal tumor or the rupture of blood-vessels by other means, are sometimes so large, that apprehensions are entertained about opening them, and a question arises whether they should be left unmolested, until the symptoms indicate that inflammatory action has set in, and it has become probable that suppuration has set in also, or whether this evil should be anticipated by an opening as soon as it has become probable that absorption is not proceeding to remove it. Upon this point men of great experience are divided in opinion; one party setting no limits to the power of nature, the other seeing evil in prolonged hesitation. This latter is the party I would advise you to join.

An abscess may be very rapid or very slow in its progress; and as it affects the one or the other character, may be termed acute or chronic. The distinction between one and the other is not, however, always evident. A phlegmonous or acute abscess may be superficial or deep seated, and upon these circumstances its characters very much depend. When it is immediately under the skin, the inflammation, which was intense, lessens; the redness and heat diminish; the pain, which was tensive and pulsating, becomes heavy; rigors are full; the tumor softens, and the cuticle is separated from the entis: there is pitting on pressure; soon a pointing is perceived at the centre of the tumor, and if pressure or percussion be carefully made, fluctuation is apparent. When the abscess is superficial, the tumor is so prominent, and its characters are so decided, that it is scarcely possible to mistake it for any thing else, except it be in the neighbourhood of joints. If deeper seated, the diagnosis is less simple; the tumor is not prominent, and the fluctuation is obscure for some time. We must then look for pitting upon pressure, in consequence of a certain quantity of infiltration; because this state is usually a very faithful index of deep-seated suppuration; it may enable you to detect deep-seated abscess by the side of the rectum long before fluctuation is apparent, and justifies us in plunging the lancet deeply

into the part, to avoid greater evils. The difficulty of diagnosis may be still greater when a purulent collection is situated under aponeuroses, and the gravity of the symptoms is increased; it may then insinuate itself between muscles, injure the periosteum, and occasion necrosis: the suppuration may, in these cases, be so considerable as to exhaust the patient, or even to require amputation. Such abscesses we see sometimes under the scalp, in the back, the loins; but they are most commonly seen in the limbs, and no where are they known to produce more intense symptoms than in the thigh, probably because of the bulk of the muscles and the strength of the fasciæ lata.

Wherever a sub-aponeurotic abscess has its seat, the inflammation by which it is preceded is announced by a deep-seated pain, by considerable but ill circumscribed, though extended, swelling of the part. There is little or no redness of the skin, and the progress of the abscess is very insidious; it exists long before fluctuation is apparent, and to recognize it even when the collection is considerable, it is not enough to press with two fingers upon each side of the tumefaction; it is necessary to make strong pressure with all the fingers or even with the palm of the hand; sometimes even it is necessary to grasp the limb with both hands a little removed from each other, and, by making alternate pressure, a feeling of fluctuation may be distinguished. Here we must especially look for the œdema and pitting upon pressure. These abscesses should be opened as soon as the fluctuation is quite manifest: we must not wait until all obscurity is dissipated, because they will extend—will burrow between muscles and tendons, denude the bone, implicate a joint, and produce enormous and irreparable mischief. To the evidence furnished by œdema and pitting, David added another, as applicable to the thigh; an excessively acute pain felt in the heel. Still there are some abscesses affecting cavities, or so deep-seated, as to be almost beyond our means of investigation. In such cases, all we have to rely on is, the irregular rigors, the remission of inflammatory symptoms, a sense of weight where an acute pulsating pain was previously felt. How often, after death, do we discover abscesses, which during life afforded none of these signs to indicate their existence!

I have already stated that commonly, when the act of suppuration is established, ordinary inflammatory action declines; the pulse becomes large, soft, and undulating; rigors occurring at irregular intervals, and affecting the back, the loins, and sometimes the lower extremities, are ob-

served, and are as much more marked as the inflammation has been decided. If the abscess be considerable, and the sympathetic action great, there is heat in the palms of the hands and the soles of the feet: the pulse becomes small and frequent, the perspiration irregular and nocturnal, the strength diminishes, and hectic fever is developed. The tumefaction which accompanies inflammation does not entirely disappear when suppuration sets in, but it is lessened at its circumference and fixed at its centre, which is raised, projects, softens, and constitutes pointing. The redness and tension take a similar course. The circumference of the inflamed mass becomes soft and natural, but the pointed part acquires a dark red or bluish colour, which increases as the integuments are thinned. Fluctuation at this period is very apparent, and constitutes the only positive local sign of the presence of suppuration.

All acute phlegmonous abscesses left to themselves, tend to enlarge. Absorption and disappearance of the tumor is rare; as they enlarge, they become more superficial, they approach the skin, "ulcerative absorption" sets in, the integuments are thinned, and one or many openings are made: but this ulceration is commonly slowly brought about; an abscess rarely opens when it arrives at maturity. It is, therefore, always prudent to substitute methodical artificial means for the tardy, and often imperfect, efforts of nature. Much is gained by anticipating spontaneous openings—much suffering spared, and the further extension of the disease is prevented. There are cases where it is urgent to open immature abscesses. Some persons are of opinion that those of the neck, the face, and the breast, should be allowed to open themselves, as a means of avoiding the cicatrix following incisions. In following this rule, you would very frequently fall into the inconvenience you would wish to avoid; because, if you leave the abscess to itself, the integuments become greatly thinned over considerable space; the subcutaneous cellular tissue is broken down and removed, or absorbed; those integuments will be broken down and destroyed before the wound will heal. I am convinced, that in those abscesses usually connected with glandular structures, we should never temporise—we should never too long delay opening them, or the present inconvenience and future deformity will be materially increased.

#### *Chronic Abscess.*

The lower the degree of inflammation by which an abscess is determined, the less appreciable are the symptoms. In fact,

such abscesses may be developed without sufficient pain, heat, or inconvenience, to arrest the patient's attention. A soldier whose knapsack is constantly rubbing against his back, is frequently the subject of these abscesses, and their existence is not recognized before the tumor has attained considerable size. The inflammatory action being low, the blood-vessels of the part are not much distended; the inflamed structures, instead of presenting many points of suppuration, which is the case when the suppurative inflammation is acute, present only a single one, and fluctuation is usually soon manifested. The pus, too, not being produced under the influence of acute action, is more serous, more flocculent, and is mixed with a greater or less number of heterogeneous materials. Sometimes, however, under these circumstances, its consistency is greatly increased. These abscesses, thus slowly developed, give time for a more perfect organization than those which are rapidly developed; the tumefaction of the surrounding tissues is more completely dissipated; the parietes are capable of more complete isolation: indeed the morbid action seems to be very much limited to the parietes themselves.

The greater number of chronic abscesses are more or less nearly connected with scrofula, and they are either subcutaneous or in the immediate vicinity of lymphatic glands: their most frequent seat is the neck and the loins. They are always preceded by a low degree of inflammation. The fluctuation may be soon apparent; so soon that Dehaen fancied pus must be deposited there by the arteries. At other times they are slow; are preceded by induration and by tumefaction, which exists some time before suppuration is apparent. In these abscesses the containing membrane is usually very distinct; its external and internal layers are well marked. Sometimes bands of cellular tissue, blood-vessels, or nerves, stretch across the cavity. These abscesses present a soft, circumscribed, indolent tumor; if not very deep, the skin may be much distended, but its colour is little if at all changed, and there is seldom decided pointing. Their pus is usually serous and flaky. It is very difficult to distinguish these from symptomatic and critical abscesses, and occasionally from encysted tumors.

Of this species of abscess there is one variety deserving of our especial attention: I mean those where pus is deposited at a certain distance from a carious bone, around which it is formed. This pus may take a direct or tortuous course through the adjoining cellular tissue. In these cases the pus is slowly formed, the disten-

sion is very gradual, and the pus is enabled to find a way for itself without doing much violence to the tissue through which it passes. Usually these abscesses succeed to caries of the bones of the trunk; it may, however, happen from a similar affection of the bones of the limbs; but certainly ninety-nine out of every hundred cases are owing to caries of the vertebral column.

If we examine the parietes of these abscesses at their origin, we find the bone more or less diseased, its substance more or less destroyed, softened, friable, darkish grey in colour. From this point a canal begins to be formed: it is hollowed out in the cellular tissue, taking vessels or muscles as its guide, and leading to the tumor which points externally. Along its course the cellular tissue is changed; it is hardened, lead-like; sometimes fibro-cartilaginous; occasionally presenting a character not unlike spermæti. At the extremity of this canal is a cavity of varying capacity, lined by a pyogenic membrane. If the disease commence in the bodies of the lumbar vertebræ, the pus may pass upwards even as far as the pharynx: it may be circumscribed, may be surrounded by a strong covering, and confined to the bodies and sides of the vertebræ; but commonly it is not confined to the spot on which it is formed: the vertical position of the body during many hours, the laxity of the adjoining cellular tissue, the continued motion impressed upon the viscera of the thorax and abdomen, are among the causes which favour the downward migration of the fluid. It may take as its guide the fibrous sheath of the psoas muscles: this is the common track when caries affects one or more of the first four lumbar vertebræ: it may pass down the centres of the muscles. Even if the caries affects the latter dorsal vertebræ the same course may be taken by the pus; passing first between the pillars of the diaphragm, it may pass down to the lesser trochanter. The collection of pus may be superficial, or deep-seated; it may be within or without the sheath of the psoas. In the latter case, at first placed under the pleura, the tumor may form in the iliac fossa between the fascia and the peritoneum: it may pass on to the crural ring, and pass through it along with the vessels: it may pass towards the anterior and superior iliac spine. I had a case not long since of a young man, of twenty, in which the pus took this course: he is now quite recovered. It may take a course through the inguinal ring (Brodie). Certain abscesses proceeding from disease of the lumbar vertebræ are presented in the lumbar region; but then the disease usually affects the transverse processes or the posterior part of the

bodies of the vertebræ. Sometimes the pus may in the same case collect in the lumbar region, and descend towards the groin. In these cases pus may take a different course; it may pass through the sciatic notch, and form a tumor under the glutæus maximus, or it may present in the perineum or by the side of the rectum. You must also be prepared to meet such tumors elsewhere: they have been presented at the anterior part of the chest, the pus following the intercostal muscles. The pus may enter the spinal canal; it has perforated the œsophagus, and been vomited up. Gooch mentions a case in which such a tumor opened into a lung; Wedemeyer describes a case in which it burst into the colon. The pus found in these collections is very unlike that of acute abscess; it is largely diluted by admixture with various substances: it is thin, greyish, or yellowish; flakes of albumino-fibrinous matter float in it, and probably masses of tubercular matter. These abscesses are slow in their progress; many months may elapse after the patient has complained of pain in the lumbar region, before pointing occurs. It has happened in six weeks; it has been delayed for two years. Brodie believes that when the intervertebral fibro-cartilages are primarily affected the progress of the disease is slower; and the lumbar pains may have ceased, and the patient's apprehensions have been dissipated, when pointing is discovered. These tumors are always soft; fluctuation is very obvious; the skin does not change colour, and they are not well circumscribed: they are not painful even on pressure. By pressing upon them they may be made to disappear almost completely. I had a case some time since in which the disease was presented in the labium: so completely did it disappear upon pressure, when the patient lay down, that it was believed by several persons to be a hernia. If there be two tumors, pressure on one will usually enlarge the other. Any effort by which the abdominal cavity is lessened increases the tension of the tumor, and as coughing does so very decidedly, a superficial observer is not unlikely to mistake the disease for hernia. Slow though it be, ultimately the integuments over the tumor become thinned; the skin reddens, and ulceration may happen. Whether opened in this way or by puncture, the quantity of fluid which escapes appears out of all proportion with the size of the tumor: the jet varies with every effort, and when most of it is evacuated, we see, on inspiration, the abdominal cavity being lessened; that more is poured out; when expiration takes place, the same cavity being en-

larged, a certain quantity of air is, as it were, aspired into the sac of the abscess. If we at once carefully bring together the edges of the puncture, as was advised by Mr. Abernethy, we are surprised often within a week to find the tumor apparently as large as it was before the evacuation of any fluid. Another puncture is made; a third, a fourth, a fifth, or even a sixth; but it is rarely that we succeed in completely closing up the cavity after the second or third puncture: the incision becomes ulcerated, or the integument is so thinned that union cannot take place, and fistulous opening remains. It is rarely that the pus which escapes after even a second puncture is so free from a decomposed smell as the first; but when a fistulous communication is established it undergoes great changes, becomes very foetid, and the system sympathizes with this change; the patient becomes emaciated, his appetite is capricious, and hectic symptoms are developed, with colliquative diarrhœas, and the patient sinks in extreme emaciation. It is not an affection which under ordinary circumstances terminates life rapidly: the tumor may not open for a couple of years after its appearance: it may be prolonged eight or twelve months after the opening has been made; usually, however, the progress is much more rapid.

It is important to inquire how those symptoms are developed by which the system, at certain periods of these large purulent collections, is so gravely affected. It is believed by many that they are a consequence of the change brought about in pus by the admission of atmospheric air: other persons have maintained that they are a consequence of putrid fermentation of pus caused by the removal of pressure. Those who support this opinion refer to the air-bubbles presented in a second or third puncture, although every care has been taken to prevent the admission of the air; these bubbles indicating, say they, a decomposition of the pus. That the pus of a second or third evacuation is totally unlike that of a first, is quite true; that the change may be produced by the action of atmospheric air upon this fluid, is possible. But how does this altered fluid so deeply affect the economy? Some persons are of opinion that pus is absorbed, and deposited in the circulating mass. To this opinion I cannot assent, because that group of symptoms produced by the introduction of pus into the circulating mass is quite unlike those which occur in these abscesses. I apprehend that the change produced in the purulent fluid is not the sole cause of those serious symptoms: the exhaustion conse-

quent upon profuse suppuration concurs with other causes to produce them. And to these we must add the inflammation of a membrane which lines so large a cavity as that of a lumbar or psoas abscess frequently is. From the first day rigors are often manifest; a very violent paroxysm of fever follows, and the parietes of the abscess become painful to the touch. There can be no question that these symptoms are owing to inflammation of the pyogenic membrane. Still the fetidity of the fluid must always lead us to presume that putrid decomposition is going on. It may be very fetid on a first evacuation: abscesses of the brain are always extremely fetid; those of the abdominal parietes are also occasionally so, even though no viscus be directly implicated. In those which are developed near cavities which may contain gaseous fluids, or in the vicinity of organs containing particular glands, this is especially the case—the mouth, the trachea, the vagina, the rectum. Whatever objections may be raised, it is very certain that the admission of air often exercises a deleterious influence upon certain parts of the animal economy. This is well shown in compound fractures; in the inflamed pleura, if the operation of empyema be then performed. All surgeons are also aware how desirable it is to exclude air from wounds. Chaussier, and the vitalists, deny the possibility of such changes in the living body; but if the concurrence of circumstances most proper to determine it—the presence in the same cavity of decomposable matter, atmospheric air, and a temperature of 100° Fahrenheit—are not sufficient to prove the fact, the odour of the fluid, the ammoniacal gas which is disengaged, its instantaneous action upon metallic instruments plunged into it, are sufficient to remove all doubt.

There are yet other circumstances besides the admission of air which contribute to produce a change, and to develop putridity in the pus contained in large abscesses. The reaction exercised by viscera irritated sympathetically after the opening, exercises considerable influence: the alimentary canal, the nervous system, and the heart, are irritated by the inflammatory action developed in the parietes of a large abscess, and under this influence pus rapidly changes, and acquires a putrid state. There are therefore two causes in action—the one chemical, the other vital. They are perfectly compatible; in fact, are almost always united in the living body: indeed, most of the phenomena of life may be reduced to chemical combinations modified by vital action. We know that fluids secreted during certain diseases are as much more disposed to become pu-

trid as the irritation or inflammation under which they have been produced has been more intense. The action of air alone does not always produce these changes, while inflammation of internal organs will excite them very rapidly. Open a symptomatic abscess not far removed from the irritation which has occasioned it: unless its cavity be considerable, fever is rarely developed, and the sanious or foetid change in the pus is not produced. But let a gastro-intestinal irritation be lit up, and the pus will soon undergo the changes we are considering. The same phenomena will constantly be observed in wounds: in all these cases, to the irritation of the denuded part is added a visceral irritation, by which fever is excited, and the changes in the elaborated fluids follow. Still the entrance of air is probably the cause of the local inflammation, and in many cases of all the ulterior accidents. We should, therefore, as much as possible endeavour to exclude it.

Although in this species of abscess the disease in the majority of cases is not discovered before pointing takes place, yet when it affects the spinal column a certain number of symptoms are present; pain, tumefaction, uneasiness; in fact, symptoms of disease from whence the pus will proceed. But these signs are not enough to satisfy us that caries is taking place: in fact, to discover that suppuration is actually going on is rarely possible in such cases until pointing occurs. It is true, when there is irregular fever, night sweats, and other signs of internal suppuration, they justify us in suspecting, especially when accompanied by embarrassed respiration, that suppuration has taken place. In such cases, although no tumefaction exist at the groin, the crural regions, or the other openings of the pelvis, it is probable that it will soon appear.

With respect to suppuration generally, we must never lose sight of one circumstance; that is, the great facility with which, in some persons, pus is formed. The slightest irritation in such persons is enough to excite it, whilst in others intense cellular inflammation may exist without occasioning suppuration. Pale, flabby, lymphatic subjects, and those broken down by previous suffering, belong to the first class; as well as those suffering from particular diseases—small-pox, gastro-enteric irritation. In such cases, and when abscesses have long existed, and are suddenly suppressed by surgical operation or otherwise, almost all the organs of the body manifest a singular tendency to similar secretions. It appears as if nature had supplied materials which must be got rid of at any cost.

## ON SYPHILIS.

BY HERBERT MAYO, F.R.S.

Senior Surgeon to Middlesex Hospital.

[Continued from page 326.]

[For the London Medical-Gazette.]

*General laws of constitutional lues recapitulated — Group of symptoms that attend siphilitic psoriasis — Siphilitic pains — Excoriation of the fauces and nostrils — Falling off of the hair — Treatment of siphilitic psoriasis — Cases.*

I HAVE represented constitutional lues as a disease having an ordinary duration of from one to two years, during which several remissions, or complete intermissions of every symptom, occur. This is, indeed, but another mode of stating that when secondary symptoms of siphilis have once appeared, they are liable to reappear several times, the whole term in which they are liable to reappear being commonly limited to one or two years.

Sometimes the duration of constitutional lues is confined to a few weeks, and to a single attack of secondary symptoms. In the other extreme, the symptoms continue to reappear at intervals for several years.

In most instances the tendency of the disease is to wear itself out, each renewed attack of secondary symptoms being less severe than the preceding. Nevertheless, occasionally the disease shews a disposition towards increasing virulence.

The first attack of secondary symptoms generally occurs between two and three months from the commencement of the primary disease; frequently, however, it occurs within a month from that period; sometimes after a year or years have elapsed.

When mercury has been used in the treatment of the primary sore, the secondary symptoms are slower than otherwise in making their appearance; and as secondary siphilis, when it occurs after the mercurial treatment, is not found to have been mitigated by it, the final recovery of the patient in these instances is proportionately delayed. This circumstance is the strongest argument that can be advanced against the treatment of chancre by mercury. It is very difficult to say which is the lesser

evil, a diminished chance of indisposition beginning and terminating at a distant period, or an increased chance of the same illness, to begin and terminate earlier.

The parts principally affected in constitutional lues are the skin, the throat, the iris, the bones. I have divided the affections of the skin into the non-ulcerative and the ulcerative; and have described of the former the appearances of roseola, mottling, and psoriasis.

I shall now proceed to describe the progress of an attack of siphilitic psoriasis, which symptom is the prominent one in the most frequent variety of constitutional lues; it is, indeed, sometimes the only symptom present. Even the slight impairment of health, which is generally observable during the whole duration of lues, sometimes here exists in a barely appreciable degree; and the patient considers that he is perfectly well but for the few spots which continue to form upon the head, the body, the hands, upon one or more parts of the cutaneous surface, new ones appearing and coming forward as the earlier ones fade. Such an attack may last for several weeks, and never recur; or, as it more frequently happens, the complaint may disappear and return after an interval. Instead, again, of a simple outbreak of psoriasis upon the cutaneous surface, there may coexist with, or precede it, other symptoms, that have now to be examined.

The symptoms that thus often group with psoriasis are (besides roseola and mottling of the skin, that have been already adverted to), siphilitic pains, excoriation of the mucous membrane of the fauces, and falling off of the hair. These are likewise, indeed, in themselves independent or substantive symptoms of lues. If often found in conjunction with psoriasis, each sometimes exists alone, or is found in other combinations. Siphilitic pains and loss of hair are equally met with both in the lichenous form of lues, and in secondary cutaneous ulceration. They are liable to go with either of these three great forms of siphilitic cutaneous disease, just as iritis, and affections of the bones, are liable to follow in the train of each.

Siphilitic pains resemble those of chronic rheumatism. Sometimes they affect the whole person; often the back and shoulders only; sometimes one part alone — the elbow, the knee, the

ankle, the shin bones. They bear no proportion to the severity of the other symptoms. Sometimes they last during a few days only; in other cases during the continuance of the eruption. They occur in the mildest forms of the disease as well as in the more serious; and in the most virulent case of psoriasis that I have witnessed they were absent. There is, however, one less usual form of psoriasis, in which they invariably precede the eruption; and being attended with constitutional disturbance, put on the characters of a protracted eruptive fever. The same thing, it is well to observe, uniformly happens in lichen. Pains sometimes occur at a remote period of time, many months or years, after primary syphilis, and are the only symptoms of the complaint developed; they are then capable of being identified with syphilis by the history of the case, and their yielding to anti-syphilitic treatment.

Mottling of the skin frequently coexists with psoriasis. The body, for instance, is often mottled, while there are patches of psoriasis on the head and hands. Sometimes, indeed, the mottling exists alone, without either psoriasis or any other symptom. It seems an incomplete effort towards the same action.

Syphilitic excoriation of the mucous membrane of the fauces and nostrils is an extension of psoriasis to these surfaces. Patches of the mucous membrane become inflamed, and are covered with a layer of thickened whitish epithelium: when this moist scale desquamates, the surface exposed is red and raw. The alternation of these appearances is best seen upon the tonsils, which are the commonest seat of the affection; they are at the same time more or less swollen. On the arches of the palate the patch remains more constantly white; upon the under part of the side of the tongue, or at its tip, the patch, on the other hand, is commonly excoriated. Upon the inside of the lip such a patch occasionally forms, of the size of a silver penny, with the same whitish appearance as on the arches of the palate. Upon the dorsum of the tongue, the same affection is attended with surrounding induration, and fissures of the surface. When a part of the lining membrane of the nose is in this state, it is red, sore, and uneasy, but there is no increase of secretion. The patches on the palate and tonsils are less

sore than those on the other parts of the mucous membrane. These appearances are sometimes the sole evidence of the existence of secondary syphilis. In a greater or less degree they are very constant attendants of cutaneous psoriasis. They generally occupy one or two only of the points indicated at a time.

After psoriasis has existed some weeks the hair is liable to begin to fall off. This I have known happen as an isolated symptom of secondary syphilis, some time after the cure of chancre by mercury. In the case of David Philips, again, given by Mr. Rose, three months after a sore of the common appearance of chancre had healed with much hardness and thickening, mercury not having been used, "the hair came off in large patches, particularly about the back of the head:" in two months it grew as strong as ever. Mr. Rose adverts to another similar instance in which, as in this, no other symptom manifested itself.

The course of syphilitic psoriasis, independently of the uncertain coexistence of one or more of the preceding symptoms with it, is extremely variable: sometimes it disappears after a few weeks, and does not recur; far more frequently it continues for many months, alternately getting better and worse; or, after completely disappearing, it returns in fresh attacks. Sometimes left without treatment, it remains for months nearly stationary. Occasionally one or more of the patches ulcerate; but the ulceration is superficial, and cicatrization speedily follows. When the disease is protracted, the eruption is likely to be complicated with iritis, and with affections of the bones.

These great diversities in the habits of this form of syphilitic disease render it impossible to lay down any invariable rule for its treatment. Where the symptoms are mild, it is better to give no medicine, but to allow the complaint to wear itself out, enjoining only great moderation in living. When it appears in a middling character of virulence, or where, being in its mildest form, it happens to disfigure by breaking out on the hands or face, it becomes necessary to resort to medicine to repel the disorder: for this purpose a course of the iodide of potassium is to be employed. In general the exhibition of the iodide for two or three weeks, in

doses of from two to ten or twenty grains three times a day, is fully sufficient to subdue the attack. I am disposed to think it very important to let the complaint wear itself out when it is possible, with little or no assistance from medicine. All that I have observed leads me to believe that the disease never strengthens itself, but, on the contrary, exhausts itself by its outbreaks. When they are repressed by the use of the iodide of potassium, or sarsaparilla, or both together, they nevertheless return after an interval; and it is far from impossible that the entire duration of the complaint may be thus lengthened. Another argument against using medicine in these attacks, when it can be avoided, is, that it is never certain in what form the disease may next make its appearance; and it is desirable to keep in reserve, against a contingent more serious attack the full force of an untried, and therefore a more efficacious remedy.

In the most virulent cases, a course of mercury may be resorted to with a certainty that it will subdue the attack. This measure is especially to be recommended, if mercury was not given for the primary disease. But mercury administered in such a case only, like the iodide of potassium, repels the present attack; the disease is not extinguished by it, but will certainly manifest itself anew; probably, however, its next re-appearance will be in a mitigated form, and then, of course, mercury is not again to be immediately resorted to.

The most effective time for the employment of mercury in syphilitic psoriasis, is when the disease has lingered on for a considerable period, having, as it may be supposed, approached its natural extinction, yet when it is not clearly on the decline (when mercury would be unnecessary), but is either stationary or progressing. The extinction of the disease, it has appeared to me, may then be accelerated by the use of mercury.

I shall now proceed to exemplify the features of syphilitic psoriasis, and its treatment, by the detail of cases; and I shall first place before the reader three, out of many given by Mr. Rose, which show the natural course of the disease in its mildest form.

John Lee, admitted Sept. 5, 1815, with two foul sores of the size of a silver penny on the internal prepuce,

which had all the characters of chancres, and had been present seventeen days. Sept. 16, a bubo had appeared in the right groin. Oct. 30, the sores healed; the hardness of the prepuce was diminishing. The bubo was dispersed. Nov. 9, he had rheumatic pains in his shoulders and arms, and a dark mottled appearance of the skin over every part of the body. Nov. 25, the mottled appearance had begun to fade, and the rheumatism was less severe. Cicatrix of the sores natural. Dec. 15, the symptoms had disappeared.

E. Hogg, admitted Nov. 13, 1815, with a deep ulcer, with hard irregular margin, on the inner membrane of the prepuce, of the size of a large split pea, with bubo in the right groin. The symptoms were of a few days' standing. Dec. 16, the sore was healed, with a great deal of thickening and hardness. The bubo had suppurated, but the matter was beginning to be absorbed. Jan. 2, 1816, a very irritable sore was again formed, from his having rubbed the cuticle off the cicatrix ten days ago. The whole prepuce was inflamed and swollen. Feb. 7, the sore had again healed. The hardness was like a piece of marble. The bubo had come forward, and had burst and healed. His skin had a dark mottled appearance on every part of his body. Feb. 28: by the use of a little mercurial ointment and camphor to the cicatrix, the hardness had a good deal diminished, but was still very considerable. The mottled skin was as before. April 16, the mottled appearance had entirely gone off. The hardness of the cicatrix remained. Sept. 21, the cicatrix was nearly natural.

Wm. Carrier, admitted May 23, 1816, with a deep foul sore by the edge of the corona glandis near the frænum, one side of which was destroyed by it. The base and margin were much indurated and thickened, and the discharge was thin and acrid. The sore was not healed till the 8th of August, and then with considerable hardness. A gland became affected in his left groin a few days after his admission, but was dispersed in about a month. July 6th, he observed some spots on his breast and loins, and in a day or two the whole body was covered very thick with dark brown patches, of an irregular form, and a little elevated, larger than the diameter of split peas, giving a mottled appearance to the skin. A few were

visible on his forehead, about the roots of his hair, and behind his ears. July 17, he began to take sarsaparilla; the appearance of the eruption had not altered. August 8, there were still some coppery spots on his forehead and about the roots of the hair, but those on the body were much fainter. August 21, the eruption was faint. Oct. 6, a dark-coloured eruption, slightly elevated, had again become more distinct on his back and shoulders. Nov. 24, his tonsils were enlarged, and looked as if covered with an additional layer of lymph. Feb. 9, 1817, the same eruption of the tonsils continued. The eruption had disappeared. Feb. 23, the tonsils were nearly natural. His health had been uninterruptedly good since the pain and irritation of the sore subsided.

I shall now narrate a case in which the symptoms were extremely mild, but at the same time intractable. They were troublesome enough to require medicine, but each medicine used was efficacious only when first tried, and afterwards proved nugatory, or disagreed. The disease finally wore itself out, under the observance of great caution in living.

A. B., when on the Continent, observed, after exposure to infection, a small superficial circular sore on the inner prepuce, near the corona glandis. In three or four days the surface of the sore became elevated above the surrounding skin. Calomel in powder was then applied three times a day for ten days, and the sore healed, leaving, however, much hardness of cicatrix. To this mercurial ointment was applied, and the hardness dispersed in ten days more. One grain of blue pill was given daily at the same time, and continued four weeks; it produced no sensible effects. Four weeks from the first appearance of the ulcer two or three spots appeared on the palms of the hands, which enlarged to irregular red patches, with desquamation: the throat became excoriated about the same time. After a few days, having returned to England, and living in society without any restriction as to diet, he recovered of the sore-throat, but the spots remained. Towards the middle of May, two months from the first appearance of the sore, the spots on the hand increased in number and size, and the sore-throat returned. In June he began to take sar-

saparilla, with liquor potassæ, and continued to do so for five weeks, when he became quite well again; he lived, besides, strictly by rule, dined at two, and drank no wine. Then he went to the sea side, continuing to live as carefully, but when there he experienced a return of the disease, for which sarsaparilla and potass were again taken, but without advantage. There were spots on the head, hands, and scrotum, excoriated throat, and soreness of the mucous membrane of the nose. A sixth of a grain of corrosive sublimate was now tried twice a day for two days, three times a day three days, four times for two days. Great amendment followed, and the hands became quite well; but depression, with faintness, and irregular action of the heart, supervened. The mercury being on this account discontinued, the spots and sore-throat returned. Towards the end of September mercury was tried again, and four grains of blue pill were taken every night for a week, with manifest improvement; then supervened diarrhœa and dysentery. The medicine being discontinued, the symptoms in a short time made progress. Then in succession other remedies were used. The decoction of sarsaparilla, the infusion of sarsaparilla in lime water, small quantities of mercurial ointment, the iodide of potassium in minute doses; all of which seemed to do good for a few days, then became nugatory; and the mercury when persisted in, disagreed. So the winter passed, upon the whole with improvement, and he left town better in health about the middle of January. Feb. 1, the psoriasis increasing again on the head and on the throat, and appearing on the hands, a sixth of a grain of corrosive sublimate was taken twice or thrice. In five days the throat was better, but he had become pale and weak: the mercury was therefore discontinued; upon which he became worse, and the oxymeriate resumed had no effect. He then lived with the greatest care and management as to diet and habits, taking no medicines, and every symptom disappeared. He is now in perfect health, but for several months after the period spoken of, any deviation from the most regular living would bring back symptoms of the disease.

The two cases which I shall next

narrate exemplify the efficacy of the iodide of potassium in subduing attacks of ordinary syphilitic psoriasis.

B. A., aged 24, was admitted an out-patient of Middlesex Hospital, for a superficial sore on the inner prepuce, which had existed three weeks: it was not indurated, but its surface was red, and the surrounding skin inflamed and angry. The black wash was directed to be applied on lint to the sore; and ten grains of the iodide of potassium, in decoction of sarsaparilla, ordered to be taken twice a day. Three days afterwards there was more inflammation about the ulcer, and the lower part of the belly was mottled with red patches of an irregular figure. Aperient medicine was given; the wash changed to a saturnine and opiate lotion, and the dose of the iodide increased to a scruple three times a day. In a few days the sore had materially improved, but the forehead was covered with red circular patches of the size of a silver penny; the belly was more extensively mottled, and the throat was excoriated. The same medicines were continued. In a week afterwards the spots had become less bright, and in four weeks more, under the same plan, they had disappeared. The sore had granulated and healed in a shorter time. This patient came again to the hospital after upwards of a year; he had a few spots of psoriasis on his head and hands, and excoriated throat, and these symptoms he said had recurred several times, but to so slight an extent that he did not think it worth while to apply for medicine. I ordered him the iodide again, and I have not seen him since.

B. C., aged about 27, had, in March 1836, a small circular sore, slightly excavated, on the inner prepuce, near the edge of the glans: it was not indurated, but upon applying the black wash for three days no change took place in its character: he then began mercury, taking for a fortnight fifteen grains of blue pill daily. This producing no effect upon the gums he used in addition half a drachm of mercurial ointment every night: the sore now began to granulate, and slowly healed towards the termination of the fourth week, when the mercury, which had never thoroughly affected the gums, but had produced paleness and night perspirations, excited erethism: he had headache, intermitting pulse, and vomiting. No further mer-

cury was therefore given. Thirteen months afterwards, through catching cold, as he supposed, when heated with exercise, he experienced pains in the shoulders, which were treated as rheumatism, but did not leave him. He then reapplied to me, when I found the abdomen mottled, and that he complained of pain, swelling, and stiffness of one knee, on which he had received a blow some months before. By my advice he took sarsaparilla, with the iodide of potassium, first five grains, then ten, three times a day, for a month, and recovered. During the following summer he was attacked with slight sore-throat, psoriasis on the legs and hands, with spots upon the head, and excoriated throat. For this he took sarsaparilla alone, became fatter, and perfectly well, and took considerable exercise in shooting. In November he had another slight attack of psoriasis; two or three spots formed on the wrist, the throat was sore, and the periosteum of one tibia: he took the iodide again for three weeks, and completely recovered. Early in the spring, when in the country, he experienced severe headaches, for which he was purged and cupped without benefit. On taking the iodide for a fortnight he became well again.

The next case which I shall narrate exemplifies a virulent outbreak of psoriasis, where the treatment of the primary sores had not been mercurial. Mercury was required to repel this attack. Other forms of cutaneous disease then followed, of a kind to the cure of which mercury was less appropriate. These and subsequent outbreaks of psoriasis in the same case, have yielded to the iodide of potassium.

A middle-aged person had been exposed to infection more than eight weeks before, when he discovered a sore upon the inner prepuce, near the glans. He shewed it to a surgeon, who assured him that it was not venereal, and gave him an astringent lotion to dry it up. Ten days afterwards, which had been spent in considerable exercise and travelling, the sore presented the following appearance:—It was covered with dark adherent secretion, and the adjacent part of the prepuce was swollen and red. The sore was about half an inch in diameter, circular, one half on the body of the penis, the other on the prepuce, as it appeared when the latter was drawn back. At the bottom, the sore

looked as if disposed to spread, by the sloughing of the cellular texture between the integuments and penis. It was not attended with pain. An ointment containing Peruvian balsam was applied on lint to the sore, an aperient given, and decoction of sarsaparilla, with four grains of iodide of potassium, ordered to be taken twice a day. In four or five days the sore had become clean, and had begun to granulate, when I discovered accidentally, the patient having no suspicion of its existence, another smaller sore on the opposite side of the inner prepuce. It was circular, without hardness, very slightly excavated, with a definite raised edge; the surface soft, vascular, and all but granulating. The same dressing was applied to it, and, like the first, it became a healing sore, and both were going on to cicatrize (which they did in three weeks, neither leaving hardness), when, in ten days from the commencement of the use of the iodide, siphilitic psoriasis broke out on the glans penis, on the scrotum, on the pubes, abdomen, and loins. The dose of the iodide was increased, but the eruption advanced, and, appearing upon the head and face, threatened considerable temporary disfigurement. At the same time, it seemed so little controlled by the means employed, that I thought it necessary to recommend a course of mercury. The gums were affected in three or four days, and the spots upon the forehead became stationary. The course of mercury was pursued for five weeks: by that time the spots had every where disappeared; but those on the forehead had left broad, yellow, circular stains, which only slowly wore out during the half year following. The character of these spots had been this: at first the upper part of the forehead looked mottled at half a dozen points near the roots of the hair; then distinct circular spots, of a faint red, were seen, a quarter of an inch in diameter; they were slightly raised and convex; as they enlarged they became less elevated, and of a darker colour—a browner shade of red; and thin scales of cuticle began to separate from them. In ten days from the termination of the course of mercury, the integument at the inner part of one eyebrow and one ala of the nose, became thickened, swollen, and red, assuming such an appearance as precedes siphilitic ulceration of those parts. The iodide of potassium was then

given for three weeks, first in ten grain doses, and finally half a drachm, three times a day. In four or five days from the commencement of this medicine, the redness and swelling of the integuments had begun to decline. A week had scarcely elapsed from the discontinuance of the iodide, when a new eruption appeared; spots broke out on the face and forehead, spreading with a red or elevated edge, leaving the centre paler: For this the iodide was recommenced, and, as it did not act as quickly as before, five grains of Plummer's pill were given every night in addition. On this attack receding, the throat became troublesome; the tonsils had already been swollen and excoriated, but now an angry superficial ulceration, with a yellow edge, spread over the soft palate: this gave way at once to a gargle of decoction of bark with half a grain of corrosive sublimate to the ounce. Next a papular eruption appeared upon the forehead and face, and afterwards psoriasis at several recurrences; but these have gone away each time upon a week or fortnight's course of the iodide, and since the first outbreak the attacks have been progressively milder. During the whole period, the patient's general health has been unaffected.

The two following cases exemplify the utility of mercury in progressive siphilitic disease commencing with psoriasis:—

A. B., about thirty, in the autumn of 1827, had (which had several times happened to him before) excoriation following suspicious connexion, which healed in a few days. In December he lost strength, his knees became weak and slightly swollen; his legs ached, and he perspired at night. Several circular red spots now appeared on the forehead and loins, for which an occasional dose of blue pill and aperients and bitters were prescribed. The mouth was not affected with the mercury. He consulted me in May 1828, when I recommended the decoction of sarsaparilla with the extract; which he took for two months, experiencing great amendment during the first, and but little in the second, at the close of which he went into the country. In August he became worse; the spots which had before become paler, ulcerating, and two nodes forming on the tibia. He took small doses of corrosive sublimate, and began to mend. On the 26th of November I again saw

him. He had now taken the corrosive sublimate about two months; the ulcerated patches were all healed but two; some of them had begun to ulcerate after the alterative course had been commenced three weeks, at which time the nodes ceased to be painful, and he lost the sense of weight, uneasiness, and aching in his knees and legs. But he thought that latterly the nodes had increased in size, and had become more tender on pressure. I therefore ordered him to take larger doses of mercury. For a month he took ten grains of blue pill every night, and five grains for some time longer. Every symptom disappeared during this course, and he afterwards remained perfectly well.

A. B., aged 26, admitted into Middlesex Hospital, October 25, 1829, in April 1828, had gonorrhœa, followed by a sore on the glans, which broke out in June. He took mercury, and the ulcer healed. His mouth was sore a few days only. In October 1828, he was seized with what he thought a rheumatic attack; he had pain and stiffness in all his joints and of the loins, and was confined to his bed a fortnight. These symptoms subsiding, psoriasis broke out on his whole person, but most on the face, shoulders, and legs: at the same time he had sore throat, which left him in a fortnight. The eruption, for which he has taken no medicine but an occasional aperient, has continued to the present time, having lasted a year; during which other symptoms have appeared. He has now spots of psoriasis that are nearly circular, and are slightly raised upon the shoulders, arms, forearms, and legs: some of them are grouped in clusters. Two situated upon the leg have recently begun to ulcerate; some of the others have ulcerated and have healed. There are two small nodes on the right tibia, a large one on the left, one on the right side of the os frontis. They vary at different times as to size and painfulness, and that on the forehead has once disappeared; it now is the most tender, and aches every evening from five to ten. He sleeps well, and has no night-sweats. The nodes on the legs have been much more painful than that on the forehead; their amendment was spontaneous. The surface of the swelling on the os frontis is smooth; that of the nodes on the tibiæ granulated.—Blue pill and mercurial frictions were ordered,

which were continued to the 23d of January, so as to keep his mouth moderately sore from the 1st of November to that time; by which the spots had faded, and the nodes on the legs had become free from pain and tenderness, and that on the forehead had entirely disappeared. There remained only brown discolorations where the larger spots had been, and some enlargement of the tibia\*.

[To be continued.]

## SMALL-POX AND VACCINATION.

DR. GREGORY'S REJOINDER TO  
DR. CONOLLY.

*To the Editor of the Medical Gazette.*

SIR,

WHEN I undertook to offer some criticisms on Dr. Baron's report, I was not aware of the obligations I lay under to him. I never could have guessed that, out of regard to my feelings, he had erased any portion of his report. In what way the scrutiny of a statistical return, intended for the public eye, would have wounded my feelings, I am unable to divine; but I feel grateful for the attention which I am sure was kindly meant. I cannot consent to be outdone in acts of courtesy, and the least return that I can make for such politeness, on the part of Dr. Baron, is to refrain from any further animadversions on his report.

It remains, therefore, only, that I discuss a few minor points with Dr. Conolly. He, in the first place, accuses me of "admirable inconsistency," in first denying, and then acknowledging the truth of Dr. Sonderland's experiments. Such inconsistency, if it could be proved as easily as it is charged, would put me to the blush, and probably cure me, for the rest of my life, of any controversial tendencies.

If, however, Dr. Conolly will do me the favour to compare the passage on which he builds his long and laboured attack, with the LONDON MEDICAL GAZETTE, Vol. ix. p. 301, column 2, line 28, he will find that the words imputed to me (commencing "the interesting fact") are not mine, but Dr. Baron's. Your printer, unfortunately, omitted the inverted commas. The only town in

\* In the last paper, p. 322, line 21, for "indurated," read "unindurated;" p. 328, line 56, for "shown," read "slower;" p. 325, line 60, for "maculata," read "maculatio."

England where this mistake was immaterial was Cheltenham, from whence Dr. Conolly writes, for Dr. Baron was there to recognize his own expressions, and detect the error of the press.

In the next place, Dr. Conolly charges me with inconsistency, in first asserting that the question of the origin of cow-pox "is of vast extent and importance," and afterwards saying it is "of no importance." I have explained the cause of the last error, and I will try to find a clue to this. In my second letter (p. 209, column 1, line 44) I stated that I was fully sensible of the value of Mr. Ceely's experiments, as a most interesting addition to the pathology of vaccinia. Where the words "of no importance" occur I have in vain attempted to discover. I drew a distinction, indeed, between pathological and practical importance, and it is probable that Dr. Conolly objects to this distinction. Be it so; we differ on this point; but Dr. Conolly will excuse me for hinting that this is not inconsistency. I differ from him, but not from myself.

I have no fault to find with Dr. Conolly's strictures on the Reports of the Small-Pox Hospital. He may view them as inaccurate, as being drawn up in a loose and careless manner, and as undeserving the attention of the Section. The very flattering manner in which those same returns have been quoted, by all the chief continental writers on small-pox after vaccination, and the remarkable uniformity in the results of our respective tables, must be put into the opposite scale. The statements were made without bias or prejudice, and so long as I continue physician to the Small-Pox Hospital, will continue to be made on the same principle. The subject has been most amply discussed in the evidence taken before the Vaccine Committee of the House of Commons, p. 128 to 134.

Dr. Conolly remarks, "that the whole history of the Small Pox Hospital, as far as vaccination is concerned, beginning with the mistakes of Dr. Woodville, in 1799, has been most unfortunate." This passage is, in substance, the same with one to be found at p. 274, vol. 1, of Dr. Baron's *Life of Jenner*, where it is said, "the atmosphere of the Small-Pox Hospital has always been unfavourable to the benign influence of vaccinia." The assumed blunders of the Small-Pox Hospital, in 1799, have

been often brought before the public by Dr. Baron, and are now repeated by Dr. Conolly. I question very much whether either of these gentlemen are aware of the light which has been thrown upon those supposed blunders, by the observations of numerous writers in the course of the last three years; but I must check myself, for I am touching on the subject which, from courtesy to Dr. Baron, I had declined to enter on. Allow me, however, to observe that such hard words as I have just quoted are calculated to wound my feelings quite as much as any which Dr. Baron could have suppressed. Yet for twelve years past I have supported myself wonderfully under the infliction. While the Small-Pox Hospital continues to advance in public favour, and to vaccinate, directly and indirectly, near six thousand persons annually, and while our file exhibits numerous letters from practitioners, in all parts of England, requesting supplies of our lymph (even before the penny postage law comes into force), I have no fear of Dr. Conolly making many converts to his opinion.

I have lastly to advert to another of Dr. Conolly's favourite charges of inconsistency, namely, that I lauded the Report of Dr. Baron at Liverpool, and criticized it in London. Now as to the facts. The Vaccine Committee met. Dr. Baron occupied more than three hours in reading a Report which he had prepared with great labour. Time pressed. The members had been already summoned to the general meeting. Though it was not all I could wish, yet Dr. Baron's report contained much new and interesting matter, and I seconded the motion that it be adopted, and I thought that in acting thus I had done a very handsome thing, considering the slights thrown upon the Small-Pox Hospital in that report. Mr. Banner, of Liverpool, can testify at what personal inconvenience to myself I waited all the next day, in the hope that some abbreviation of the second reading might give me an opportunity of making a few comments. Dr. Baron, however, did not conclude till the dinner hour arrived. I may be wrong, but it seemed to me that the strictures on the Report were as little desired then as they are relished now. After dinner, I spoke of the labours of Mr. Ceely, and of the spirit which animates the Provincial Association, in that strain of eulogy

they so richly deserve. I was not aware that I had said one word about Dr. Baron or the Report. Fortunately, however, for the benefit of the curious in this matter, a full report of my speech was published in the Worcester Journal. If I did allude to the subject, I probably lauded Dr. Baron's zeal in the cause of vaccination, his untiring energy in the support of Dr. Jenner's views, his great exertions in producing a Report which might be worthy of the age, and of the Provincial Medical Association, of which excellent qualities (besides many others) I have never to my knowledge attempted to deprive Dr. Baron either here or elsewhere.

I am sorry to perceive in Dr. Conolly a wish to divert into another channel a discussion which I commenced in the hope of elucidating some obscure and disputed points in vaccine pathology. Profiting, however, by the lesson which he has taught me, I shall be careful in future, when I have occasion to address you on such topics, to follow the more prudent course of your correspondent Scrutator, and to adopt such convenient cognomen as Medicus, M.D., or Non Nemo.

With many apologies for this intrusion, which, however, is positively for the last time this season,—I am, sir,

Your obedient servant,

GEORGE GREGORY.

31, Weymouth Street,  
Nov. 23, 1839.

---

SCRUTATOR'S REPLY.

*To the Editor of the Medical Gazette.*

SIR,

FROM the first introduction of vaccination in 1799, the friends of Dr. Jenner have endeavoured to brand every man as an enemy to his species, who has ventured to doubt for one moment that the whole of the statements of Jenner were correct. Now, sir, I ask whether this is a legitimate way of conducting a scientific inquiry? Dr. Conolly repeats, for the fiftieth time or more, in the GAZETTE of last week, the story of his party against Dr. Woodville. I contend that Dr. Woodville, as physician to the only Small-Pox Hospital in England, had a perfect right to receive the new practice with caution, and to make the experiments, which he did make; nay more, that the public and the profession

had a right to expect that he should make them before he took for granted that the statements of Jenner were correct, so far as could then be ascertained. Suppose the case otherwise; suppose the conclusions of Jenner to have been wrong, although made with the best intentions, and that Dr. Woodville had received them on the word of Jenner without further inquiry: would not the public then, and with justice, have had cause to complain of the proceeding of Woodville in adopting, without examination, such an important change as the first introduction of vaccination undoubtedly was? And because Dr. Woodville dared to make these experiments—to do, in fact, what common sense and common prudence dictated, his mistakes, as they choose to call them, and the hospital to which he was attached, have constantly afforded food for invective for forty years afterwards. I think it most likely that the eruption which followed those experiments of Dr. Woodville was nothing more than the vaccine lichen, a sequence of vaccination with which we are perfectly familiar now, but which was not known at that period.

The valuable information collected at the Small-Pox Hospital of late years, with regard to vaccination, is of the highest importance, and I do hope that the medical officers will continue in the same useful line of inquiry. The public have a right to look to them now for evidence of the test of vaccination that time gives, as they had a right at first to expect of Dr. Woodville the test he resorted to. So long as the results of their inquiries are confirmed by the returns of a large body, such as the army, by the careful inquiries conducted in the British Islands, such as those at Ceylon, and the experience of the Continental States, the shafts aimed at them from Cheltenham must fall powerless.

It is quite time that the subject ceased to be a party question; it has been conducted on all sides from the first in a way quite unworthy the high character awarded to Englishmen for their candour and honesty in scientific research.

For myself, with evidence before me that vaccination affords almost complete protection against small-pox in the early period of life, and that 10 per cent. only have died in the Small-Pox Hospital in the worst year yet record-

ed\*, and 12 per cent. in the British army, whilst in the unprotected 30 per cent. at least die; I think we have every reason still to place the greatest reliance on vaccination, and ought to endeavour to find out a means of protection after puberty, equal to that given in early life. I find fault with the Vaccination Report of the Provincial Association because it is not marked by that freedom from bias which ought to have distinguished a production emanating from a body of professional men, delegated to examine a great pathological question.

When unfair attempts are made to bolster up a cause—it matters not whether it be that of vaccination or any other, persons are apt to suppose that there is something wrong about it, or its advocates would feel confidence in allowing it to rest on its own merits. Vaccination is still a very great blessing, when shorn of all the false attributes that its injudicious friends of Cheltenham have given to it, such as the good sense of Jenner I am sure would not have allowed, had he lived at this period, and it may well be doubted whether they have not done the cause of vaccination more harm than good, by exaggerating the real amount of protection that it affords.

The writers of the Report have not only failed to give any collective account of persons attacked by small-pox after vaccination, in the provinces of England, and the rate of mortality deduced therefrom, but they have tried very unwisely to make it appear that small-pox is as frequent in its occurrence after small-pox as after vaccination (page 66 and elsewhere).

They have given several very loose statements to sustain their position, none of them evidently collected with that care which ought to have been bestowed on a subject brought forward against a generally received opinion, and one which I hesitate not to say, upon a tolerably extensive acquaintance with the subject, is a correct one, viz. that a second attack of small-pox is comparatively of rare occurrence, and one that ought to be considered an exception to the general rule.

The writers of the Report have given

an account, by mistake, of 297 persons at Norwich who had small-pox a second time; this error has already been pointed out, but coupled as it is with the bias of the writers, it ought to have been mentioned at the same time that they have actually stated in what way these patients had the disease, which could not have been an error in quotation. They wish it to be believed that this mistake is the only one in the Report, a point that I by no means cede to them. At page 35 they make a mistake of 7 patients in their enumeration, and at page 47 another mistake of 19, and again at page 65 there is a slight error in the return from Edinburgh.

Dr. Gregory has very properly remarked, in one of his letters in the GAZETTE, that undue stress has been laid in the Report on the recurrence of small-pox. So I should say, and I would cite the return of Mr. Goelden of Maidenhead, as an example: he says (p. 66) that "he has seen between 80 and 90 cases of small-pox after small-pox." Now I have examined returns of several thousand cases which have occurred at Ceylon, the London Small-Pox Hospital, the Royal Military Asylum, &c. and find that  $5\frac{1}{2}$  in a 1000 have small-pox a second time. Granting this to be correct, and as taken in the mass it doubtless is, or nearly so, it follows that Mr. Goelden has seen between 15,000 and 16,000 cases of small-pox, which in forty years, the time he has been in practice, I find exceeds by about one half the number admitted, in the like period, at the London Small-Pox Hospital\*.

The fair advocates of a cause, more particularly a scientific one, not merely matter of opinion, but admitting of demonstration, state openly both sides of the question. Have the triumvirate of Cheltenham done so in preparing their Vaccination Report? I answer no, without fear of contradiction, or they would have given us the returns from different parts of England, as well as the extensive information collected by Dr. Heim in Germany, by Dr. Möhl in Copenhagen, by Dr. Kinnis in Ceylon, and that at the Small-Pox Hospital in London, agreeing as these reports do in

\* See Report from Small-Pox Hospital, MED. GAZ. Vol. xxiii. p. 763.

\* See Report on Small-Pox Hospital, in Parliamentary Returns, 1826, and MED. GAZ. annually since.

the essential points of their results, and affording altogether a larger body of evidence on the true protection given by vaccination than can be found elsewhere at the present time in the world. This information, too, be it remembered, collected by individuals holding public appointments, under the controlling eye of their colleagues and other professional brethren always about hospitals, and the particulars collected *gradatim*, and entered in the registers as the cases present themselves; and when thus fully considered are less likely to be prejudiced than reports from individual practitioners.

I have taken considerable trouble to examine the returns made at various periods from Denmark, Sweden, Württemberg, Ceylon, the London Small-Pox Hospital, and the British army, and find that there is an average mortality of 8 per cent. from small pox after vaccination; the mortality varying with the violence of the epidemic of late years between 4 and 14 per cent.; but it would no doubt be much greater during a very fatal epidemic, such as those of 1781 and 1782, and 1821. The Registrar-General reports, that in the first half year of registration of deaths in England and Wales, 5811 died of small-pox; this doubled for the year makes 11,622. For many years past the mortality in the Small-Pox Hospital amounts, on an average, to 25 per cent., or a fourth of all admitted, vaccinated and unvaccinated. Thus, then, if we multiply 11,622 by 4, we get 46,488, the number of persons attacked by small-pox in England and Wales in the first year of registration. During a series of years about 40 per cent. of all patients received at the Small-Pox Hospital have been vaccinated; and this might be supposed to be about the number protected by vaccination in England at the adult period of life, allowance, of course, being made for the upper and middle classes, who are nearly all protected by vaccination, and who do not apply to hospitals in case of illness, but who are, nevertheless, liable to small-pox after a few years, as well as their poorer brethren who have been vaccinated, as many living can testify. It will be observed, on the one hand, that not many children are received into the hospital, and, on the other, that the patients are usually of the poorest

class, and the least likely, in a mass, to be protected by vaccination. The short statement of Mr. Dodd, of Chichester, in the Vaccination Report, one of the secretaries of the Provincial Association, may be considered in a great measure to confirm this statement from the Small-Pox Hospital. Mr. Dodd gives the particulars (page 47) of 220 cases (so far as I can understand from the careless way in which the Report has been got up), and of these 116, or rather more than half, had been vaccinated. Hence it may be supposed, in the absence of more accurate information, that from 40 to 50 per cent. may be about the number vaccinated in England: this return of Mr. Dodd's, and the account of the experiments of Mr. Ceely, being nearly the only things of real value in the Report.

As small-pox was epidemic in England in 1837 and 1838, it would have been very interesting to have known the numbers attacked by small-pox after vaccination in the first year of registration, and the proportion of severe and fatal cases. This information could have been supplied, in a great measure, by a well-organized Provincial Association. We should soon then arrive at "the real merits of vaccination," which, with all deference to Dr. Conolly, I beg to say we have not yet arrived at.

It is proved, then, I think, beyond doubt, that the Report of the Vaccination Section of the Provincial Association cannot be referred to as an authentic document, because of its numerous and palpable errors, to say nothing of others, from the specimens I have given, which may reasonably be presumed to exist.

I shall now take my leave of you, with many thanks for your impartiality in inserting these letters. Enough has been said, I hope, to prevent the Report from misleading the profession on points of practical importance. If I were inclined to say more about it, I should offer my dissent altogether from the opinion given at pages 71 and 72, on the subject of re-vaccination.

I have the honour to be, sir,

Your obedient servant,

SCRUTATOR.

London, Nov. 25, 1839.

## EGG AND FLOUR SPLINTS.

*To the Editor of the Medical Gazette.*

SIR,

HAVING read in the "Lancet" of Oct. 26, under the title "St. Bartholomew's Hospital," some observations upon the application of the "Immoveable Apparatus," I think it as well (if you will permit me through the medium of your valuable journal) to guard those who may have perused the paper alluded to, against placing *entire reliance* upon all therein contained, inasmuch as they may, by so doing, run considerable risk of causing their patients not only great suffering but subsequent deformity of the fractured limb.

It is not my intention, on this occasion, to enter into any discussion upon the applicability of the immoveable apparatus, neither do I desire to quarrel with the general observations of the anonymous writer, but I must differ with him as regards the term he applies to the preparation of egg and flour, as usually employed at St. Bartholomew's Hospital, in the formation of the above mentioned apparatus; and more especially as regards the preference he gives to other compositions.

The few remarks I intend to make, should they, through your kindness, become public, I consider of no small importance, since I flatter myself that they may be of some benefit to those who have seen as yet little or nothing of this mode of treating fractures.

Allow me to say that I have drawn the following conclusions from the experience I have had, and the favourable opportunities that have fallen in my way of watching the operation of the immoveable apparatus as variously prepared.

I do, then, unhesitatingly pronounce the splints, formed by a composition of egg and flour (and which is by no means "a nasty mess," when used by those who are tolerably apt with their hands), as by far the most fitting for supporting fractured limbs; moreover, should this composition be "a nasty mess," I should still urge upon those who are inclined to follow this practice of treating broken bones, its great superiority over all others, and for the following most important reasons: viz.

that the splints thus made retain their shape, solidity, and stiffness, both against heat and moisture, much longer than those formed by any other preparation.

It might be asked, where is the danger of splints becoming softened by either heat or moisture in cases of fracture, unless purposely applied? To which query I may give the following answer: that I have seen more than one case in which a simple fracture became compound; great displacement of the fractured bones, and ultimately considerable deformity of the limb; accidents which followed solely in consequence of the splints becoming completely softened by perspiration; the said splints being in one instance composed of starch and isinglass, in another of gum and whiting, and in both instances rollers soaked in starch were applied around them, thus fixing them firmly upon the limb.

I may further state that I have subjected pieces of bandage, soaked in these various preparations, both to heat and moisture, and I can safely assert that those (as I have before said) composed of egg and flour, and for which I am a decided advocate, withstand both processes much longer than any other preparation hitherto employed.

Such being the fact, this composition must be allowed to be the best suited for the formation of splints, and highly beneficial in many cases, the applicability of which depends upon their solidity and close and careful adaptation to the injured limb.

Apologizing for occupying so much of your valuable space,

I am, sir,

Your obedient servant,

BENJAMIN BARROW,

House Surgeon to St. Bartholomew's  
in 1837 and 1838.

5, St. James's Place, St. James's,  
Nov. 9, 1839.

## DYSMENORRHEA,

ACCOMPANIED BY INFLAMMATORY CONGESTION OF THE CERVIX UTERI, EFFECTUALLY RELIEVED BY SUPERFICIAL SCARIFICATION OF THAT PART.

*To the Editor of the Medical Gazette.*

SIR,

I AM anxious to communicate the following case, and its treatment, as I have

reason to believe that the scarification of the cervix uteri, in these painful cases, is nearly, if not entirely, an original suggestion, especially with regard to abstracting from it a definite quantity of blood. Dr. Ashwell saw the case with me, and was much pleased with its effects. He requested that the operation might be repeated as circumstances required.—I remain, sir,

Yours respectfully,

J. L. FENNER.

15, King's Row, Pentonville,  
Nov. 9, 1839.

Mrs. —, a widow, æt. 39, had been long afflicted with dysmenorrhœa, accompanied with inflammatory congestion of the uterus, dating its origin many years since, from a severe and protracted labour. The nervous system was so entirely implicated in this affection, that the superior and inferior extremities, as well as the body, were continually agitated by a species of chorea. She was passing through a three months' course of mercurial friction, and had found no relief from opium or any kind of narcotics. Leeches alone, applied round the cervix uteri, had palliated her sufferings, and these acted like enchantment, dissipating every symptom, and, after restless nights, producing a calm refreshing sleep of some hours' duration.

Nov. 1, 1839.—Appreciating the relief obtained from the abstraction of blood, and its tendency to remove congestion, it struck me as quite practicable, aided by my cylindrical tubular speculum (described in the *MEDICAL GAZETTE*, May 25, 1839, and may be seen at instrument makers), easily to abstract, by slight scarifications of the cervix uteri, any quantity I might think desirable. After a few superficial scarifications the blood trickled freely, and, in a quarter of an hour, two ounces and a half (by weight) were obtained, and the tube withdrawn, when the bleeding immediately ceased. Precisely the same relief followed, with uninterrupted sleep, as was wont to result from the application of leeches. The patient said that the operation was so painless that it would not even have disturbed her sleep. Dr. Ashwell saw the patient with me, and requested that the operation might be repeated, as it seemed to have been very beneficial.

2d.—Two ounces and a half of blood were obtained under the same circumstances.

3d.—Three ounces and a half of blood.

5th.—The cervix uteri having many marks of scarification, the tube was withdrawn a little, so as to expose the *cul de sac* of the vagina. Scarifications were made, presuming that it would bleed freely, because to that part of the vagina leeches have been applied by tubes perforated at the end with holes, and unscientifically thrust up the vagina; but such tubes cannot be duly applied to the cervix uteri, though sometimes to a portion of its side. The blood trickled freely, and in a quarter of an hour four ounces (by weight) were obtained, with the same relief as by leeches.

9th.—The patient having obtained more decided relief than on any former occasion from the application of leeches, the scarification is to be resumed as occasion may require, and the mercurial friction to be continued to the given time.

I have performed this operation on two other patients, and, since writing the above, have abstracted five ounces of blood (by weight) from the cervix uteri.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

---

*Changes produced in the Nervous System by Civilization, considered according to the Evidence of Physiology and the Philosophy of History.* By ROBERT VERITY, M.D., &c. Second Edition, enlarged. London, 1839. 8vo. pp. 143.

THIS work may be considered as a short essay on one point in the philosophy of history, namely, the progress of civilization. One race of man mingles with another, and by intermarriage, peaceful emulation, or even hostile collision, they improve in talent and virtue. According to Dr. Verity, their brains improve with their characters; and he speaks of a deficiency of formative power which “resided in the intellectual and huma-

nitary nature of ancient society; a deficiency perfectly conformable to corresponding wants in the Roman, Greek, Egyptian, and Hindoo types of cerebral system, namely, their inferiority to the Germanic type in the upper convolutions, and coronal region of the brain."—P. 21.

Moreover, as there has been a change of temperament in the mass of society, the nervous now bearing a greater proportion to the vascular system than it formerly did, the medical axioms of remote ages cannot be applied without modification in the present times. It strikes us that an exclusive devotion to Hippocratic or Galenic modes of practice is by no means the error of the day. Yet this warning may be useful to those who disregard the temperament of the patients for whom they prescribe, and practise upon a lymphatic constitution as if it were a sanguine one. The errors of Broussais arose, according to Dr. Verity, from his having been an army surgeon; so that he used the same method of depletion with the feeble citizen which succeeded so well with the stout soldier.

There is not much physiological matter in our author's book: the following passage, however, comes under this head:—

"It has now, indeed, been fully established by the researches of modern physiologists, that the visceral ganglionic system, the medullary columns of the spinal cord, the annular protuberances, and other cerebral ganglionic expansions, together with the numerous complex formations at the base of the brain; that the cerebellum, and the middle and posterior lobes, with but a rudimental or deficient expression of the anterior ones, and of the upper convolutions of the hemispheres, are those parts of the nervous system which, subserving chiefly muscular and animal activity, predominate and characterize the lower exemplar of type. The base of brain predominates.

"Such are the brains of savage tribes, and the degraded characters of even civilized populations; such also are the brains of those found in the prisons, at the galleys, and the penal colonies, &c."

This seems natural, but where are the data to be found? Who has dissected the brains of fifty convicts, and compared the size of the lower parts with

that to be found in the brains of fifty honest men?

On the whole, Dr. Verity's essay has its merits as a rapid sketch of the history of races; but it would be much improved if the style were more simple, and the facts given more in detail.

*The Modern Treatment of Syphilitic Diseases, both Primary and Secondary: comprising an Account of the New Remedies, with Numerous Formule for their Preparation and Mode of Administration.* By LANGSTON PARKER, M.R.C.S. &c. London, 1839. 12mo. pp. 158.

THIS little work is a useful compendium of the practice of some French surgeons, chiefly Ricord, Cullerier, and Desruelles, in the venereal disease; but the author frequently gives the opinions of the late Dr. Wallace, and sometimes his own, so that the treatment is not exclusively French. The sections on the non-mercurial treatment of syphilis will be especially instructive to English readers. Mr. Langston Parker himself appears to be a moderate mercurialist: we confess ourselves to be extremely moderate ones; so much so, as to be somewhat cooler than lukewarm: and when we read, as we do in our author (p. 18. note), of one practitioner who thinks that a mercurial course should last twenty-five or thirty days, and of another who says that moderate ptyalism should be kept up for a month, we begin to think of Le Sage and Moliere, and of the adage which speaks of remedies worse than the disease.

The following is an account of one of the new remedies, with the forms of its administration in syphilis.

#### *The Cyanuret of Mercury.*

"The cyanuret of mercury is now frequently employed in preference to the bichloride, and for the following reasons. It is more soluble and not so liable to decomposition, acts more quickly, and does not occasion those pains in the stomach and bowels that so frequently accompany the prolonged administration of the bichloride. According to the researches of M. Parent\*, the cyanuret of mercury is not decomposed by either acids or alkalis, nor by decoctions containing azotised principles or gallic acid.

\* Revue Médicate, Août, 1832.

The cyanuret of mercury may be administered internally in pills, or in solution, and used externally in the form of pomade or ointment. M. Cullerier employs the cyanuret in primary syphilis. Externally it is an extremely useful application to various forms of herpes, particularly that form termed by Alibert "herpes squamosus," the violent itching and irritation of which it allays. It may be employed externally also as a dressing to indolent syphilitic ulcers, and scirrhous tubercles, or as a gargle in ulcerations of the throat. The dose of the cyanuret is from 1-16th of a grain to a grain.

#### *Gargle of the Cyanuret of Mercury.*

R. Hydrargyri Cyanuret. gr. x.  
Infus. Lini Comp. ℥j. M.

#### *Pills of the Cyanuret of Mercury.*

R. Hydrargyri Cyanuret. gr. viij.; Pulv. Opii, gr. xvj.; Ext. Guaiaci, ʒij. M. ft. Pil. lxiv. Cap. 1 ter die.

#### *Ointment of the Cyanuret of Mercury.*

R. Hydrargyri Cyanuret. gr. xij.; Adipis, ʒj. M. ft. Unguentum.

#### *Solution of the Cyanuret of Mercury.*

R. Hydrarg. Cyanuret. gr. vj. ad gr. x.; Aquæ, ℥j. M.

Half an ounce for a dose, administered in a mucilaginous vehicle or with the addition of sugar in form of syrup.

#### *M. Parent's Cyanuretted Pills.*

R. Hydrargyri Cyanuret. gr. xxiv.; Ammoniac Murialis, ʒij.; Guaiaci Gummi, ʒij.; Ext. Aconiti, ʒij.; Ol. Anisi, ℥. xxiv. M. Mucilagini, q. s. ft. Pil. 400.

One or two twice or three times a day, the dose gradually increased. Each pill contains about 1-16th of a grain of the cyanuret. These pills are a substitute for the bichloride of mercury in many forms of secondary syphilis.

#### *Another form of M. Parent.*

R. Hydrarg. Cyanuret. gr. vi.; Opii, gr. xij.; Micæ panis, q. s. ft. Pil. xcvj.

Each pill contains 1-16th of a grain of the cyanuret adapted to forms of primary syphilis. The dose of one or two pills twice a day in the commencement and gradually increased.

We do not know whether the following formulæ will really cover the hateful

taste of capivi, or whether, after all, one must have recourse to the *capsules gélatineuses*.

#### *Mixtures.*

R. Balsam. copaibæ, ʒj.; Mucilaginis gummi acaciæ, ʒij.; Vini Xerici, ʒiv. M. (Val de Grace.) A fourth part twice a day, or more frequently.

R. Balsam. copaibæ, ʒi. ad ʒij.; Aquæ, ʒiv.; Vitelli ovi, No. 1.; Liq. opii sedativ. ℥. x. ad xx. M.—Cullerier. The quarter part, or more, night and morning.

R. Balsam. copaibæ; Syrup. tolutanos.; Mucilaginis gummi acaciæ, aa. ʒj.; Aquæ rosæ, ʒij.; Sp. ætheris nitric. ʒij. The quarter to the half, night and morning.

R. Aquæ menthæ pip.; Sp. vini rect.; Balsam. copaibæ; Aquæ aurantii, aa. ʒij.; Sp. ætheris nit. ʒj. M.—Chopart. Two large spoonful, three times a day.

R. Resinæ copaibæ; Sp. vini rect.; Syrup. bals. tolutan.; Aquæ menthæ pip.; Aquæ aurantii, aa. ʒij.; Sp. ætheris nit., ʒij. M.—Chopart. Three or four large spoonful, night and morning.

#### *Pills.*

R. Sapo. Hispaniolæ, ʒij.; Balsam. copaibæ, ʒj.; Pulv. glycyrrhizæ, q. s. ft. pil. 120. Dose.—From 15 to 40 a day, at intervals.

R. Ext. catechu, ʒss.; Bals. copaibæ, ʒij.; Terebinthinæ chiæ, ʒj.; Sanguinis draconis, ʒss. M.

To be made into pills or boluses of ten grains, from ten to thirty of which are to be taken daily, at intervals."

We omit, for want of room, other forms containing cubebs and capivier in combination, a syrup of cubebine (or rather extract of cubebs), and the lozenges of the same.

The diction of this work is in general good, though sometimes betraying marks of its French origin. "Syphilographers" is a bad word for "writers on syphilis;" and "nitrated acid of mercury" (p. 83, note) is wrong; it should be "acid nitrate of mercury," *i. e.*, supernitrate of mercury. Mr. Langston Parker's book is judicious and well-timed, and will save many practitioners from the erroneous dulness of routine.

*A Treatise on Obstetric Auscultation.*

By DR. H. F. NÆGELE. Translated from the German, by CHARLES WEST, M.D. Graduate of the University of Berlin. London, Renshaw, 1839. 12mo. pp. 120.

WHEN we consider the difficulties that often exist in determining the important fact of whether a woman is or is not pregnant, it must be a matter of some surprise that the subject of obstetric auscultation has met with so little attention from practitioners of midwifery in this country. By the German and French writers much valuable information has been afforded, which proves, upon evidence that cannot be doubted, that if the use of the stethoscope does not, and perhaps cannot, demonstratively determine the existence or non-existence of pregnancy in all cases, it will, in the very great majority, leave but little doubt upon the mind of any man whose ear has been well practised to the use of the instrument. Feeling as we do the great importance of this modern mode of investigation, and knowing its real value from our own experience, we cannot but regard the translation of Dr. Nægele's work by Dr. West as a very useful addition to our literary stock. It possesses the rather unusual advantages, from a German writer, of being concise and entirely practical. No speculations are introduced to interrupt the brief and clearly related conclusions derived from the use of the stethoscope in six hundred cases, and therefore we can recommend it to the attention of either students or practitioners. Dr. Nægele considers it a matter of indifference as to what kind of stethoscope is employed. An unpractised examiner should take care that the room is perfectly quiet, and the period of digestion should be avoided by the beginner, as the noises then heard in the intestinal canal are very likely to disturb and perplex his ear. The patient should generally lie upon her back, and be thinly clad. For the terms *bruit placentaire*, *souffle placentaire*, &c. Dr. N. prefers, and upon very good grounds, the expression of "uterine sound," which his experience has taught him is seldom sufficiently distinct to be clearly recognized before the fourth month of pregnancy. It was audible in 20 of 35 patients at the 15th week of uterine gestation: in 3 only at the 14th week.

Sometimes it cannot be distinguished till the beginning of the fifth month, but it can always be heard several weeks sooner than the pulsations of the fetal heart. The sound which proceeds from the fetal heart consists of a rapid succession of regular short pulsations, generally about twice as quick as the adult heart. The frequency of the fetal heart's pulsation, as deduced from a comparison of 600 cases, averages 136 strokes in the minute. It sometimes sinks to 90. Various and satisfactory proofs are given that considerable alterations may take place in the circulation, without at all influencing either the strength or the rhythm of the pulsations of the fetal heart. In natural labours the action of the fetal heart undergoes no evident alterations either in the force or in the rhythm of the pulsations. After the rupture of the membranes the pulsations become more distinct, because the uterus now envelops the fetus closer, and the sound is more clearly conveyed to the ear. In the early stage of pregnancy the sounds produced by the movements of the fetus may occasionally be distinguished as gentle taps repeated at intervals. These sounds may be distinguished several weeks, Dr. N. assures us, before the mother becomes conscious of the motion of the child, and earlier than the pulsations of the heart, or the uterine souffle. Certain sounds produced by the umbilical cord are also noticed. But although the pulsation of the fetal heart cannot be distinguished till a later period than the other signs of pregnancy detected by an auscultation, it is the most valuable of all, as it is evident when the proofs which manual exploration affords are either absent or inconclusive; and it is so readily perceived that even the unpractised ear usually detects it with ease. In the first stethoscopic examination we ever made, we had a proof of this fact; for we found no difficulty in hearing and counting the pulsations of the fetal heart. The patient was at the fifth month of her pregnancy. We place the more confidence in Dr. Nægele's statements and opinions, because we do not find him "run riot" in praise of obstetric auscultation to the exclusion of other modes of examination. "Auscultation can never supersede manual exploration, nor render it unnecessary: the former is a valuable auxiliary to the latter, and the results obtained by combining

both, assist us in arriving at definite conclusions." As it is not our wish to supersede the necessity of perusing the work itself, by giving a detailed abstract of its contents, we close our notice of it, by assuring our readers that they will find it to contain a clear and concise account of all the practical points connected with the subject.

*A few Minutes' Advice to Deaf Persons.* By a SURGEON AURIST. London, 1839.

AFTER all, reviewers are necessary evils—middlemen required by the frailty of human nature between writers and buyers of books. What numbers of readers we shall save the trouble of finding out that the hundred and ninety-six little pages before us contain scarcely two minutes' advice to the deaf, the bulk of the book being merely a critique on other ear doctors. When our author attacks the common herd of advertising aurists, he is in the right, generally speaking; though we cannot say that he wields the critical knout with much dexterity. But when he runs a-muck against Kramer of Berlin, it strikes us that he runs against a stone wall; for instead of saying with our author, that Kramer "appears desirous of raising himself to eminence, in the opinion of the popular world, by depreciating every other practitioner" (Preface, p. vi.), we should boldly affirm that he is desirous of raising himself to a high station in the medical commonwealth by a scientific treatise on deafness; and that he has succeeded in doing so.

Our author says, when talking of Deleau, "Probably if him, Kramer, and some of their imitators, were to read with attention the dialogue between Hotspur and Owen Glendower, in the works of our immortal bard, it might teach them to be less egotistical." (pp. 84, 85.) And then follows a quotation, "Know that at my birth," &c. Now, as it does not appear that either of these aurists asserts that his birth was signalized by an earthquake, we fear they might both read both parts of Henry IV. smack through, without any lessening of their self-approbation. If your ordinary ear-doctors, whose names are to be found on walls and palings, but not in the Temple of Fame, are to be reformed by quotations from Shakespeare, we should rather cite the pas-

sage where Macbeth speaks of certain juggling fiends,

"That keep the word of promise to our ear,  
And break it to our hope."

Had the author subjected this work before publication to the revision of some literary friend, its style and grammar might have been much improved.

*Elements of Natural Philosophy, being an Experimental Introduction to the Study of the Physical Sciences.* By GOLDING BIRD, M.D. F.L.S. F.G.S. &c.

WE are not aware of there having hitherto been any treatise on natural philosophy in the English language sufficiently simple and elementary for the student, with the exception of Dr. Arnott's *Elements of Physics*, the first part of which we introduced to our readers in one of the earliest numbers of our first volume, and which, we regret to say, at this very long interval of time, remains still unfinished. The appearance of Dr. Bird's work, however, renders this less a matter of regret, as the student has now all that he can desire in one neat, concise, and well-digested volume. The elements of natural philosophy are explained in very simple language, and illustrated by numerous woodcuts, so that the student who but gives his attention to the subject can have no difficulty in fully understanding it. The volume is, moreover, provided with an excellent index and an analytic table—no mean recommendations. There are a few errors of the press, which the student would do well to correct from the list of errata before he begins his perusal.

## MEDICAL GAZETTE.

Friday, November 29, 1839.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."  
CICERO.

## MEDICAL ETIQUETTE.

THE anecdote books of the last century inform us that when a stranger enters a room, the first question asked about him varies according to the country in which the room happens to be situated. Thus in Germany people used to ask whether

he was of noble descent for sixteen generations, in Holland whether he was solvent, in France whether he was received at court; and in England the prosaic question was, "how much has he a year?" These distinctions are instructive, and bear the stamp of truth. An obvious corollary which flows from them is, that in the Germany and France of that age, a formal treatise on etiquette would hardly be wanted; or, at least, would be much less required than in England and Holland. For if society is divided into two classes only, the *gentilhommes* and the *roturiers*, each man from his birth naturally falls into the usages of the great division to which he belongs; and as there are but two classes, patrician and plebeian, manners will necessarily stand out in strong contrast to each other. The few who are raised from the *plebs* to the *gentes* will obtain some grave advice as to behaviour from their peers, and the changes required by their elevation are so clear and indisputable, that they will need no half-crown monitor, by way of flapper, to awake their attention.

In England, on the contrary, instead of two classes, there are a dozen, and almost as many standards of politeness. The ingenious but hasty author of the *Bubbles from the Brunnens of Nassau*, mentions several of these subdivisions; such as stumpy old-fashioned English manners, black-stock military manners, and others; each school even giving its own peculiar tinge. Now, amid such an anarchy, or rather such a variety of governments, it is necessary for a well-meaning man to obtain the code which governs any new society he enters, lest he should offend in tone, gesture, or dialect. Hence in this country we have long had manuals of politeness; and unless we make allowance for the internecine war waged between different coteries, and the relics of antique rusticity which may still have survived in some of them, certain pre-

cepts and warnings would not fail to surprise us. Thus we find no less a man than Lord Chesterfield cautioning his son against the manners of the school to which he was sent, and telling him in writing not to pick his teeth with his fork. In a manual published some forty years ago (we believe by Dr. Trusler) the reader is taught to ask the lady of the house at dinner to take wine, and other elementary matters of a like nature; the book having probably been written at a time when national prosperity was pushing up masses of the people into a higher segment of the social circle, and the *ci-devant* journeyman spinner found himself not quite at his ease as a master. Now if any section of society requires a hand-book for its own peculiar instruction, it is our profession. Time, and the progress of events, have changed its position in the state, and its new place is scarcely fixed. Add to this, that the relative situation of its members is unsettled, and you will have a fine field for a medical legislator, a teacher of minor morals. *Exoriare aliquis*.

Some one indeed has arisen,\* but we have our doubts whether he is quite equal to the task which he has imposed upon himself. In the first place Mr. Banks is somewhat fretful and impatient, and forgetting that he is writing on etiquette, occasionally talks as if he was chastising a felon.

In his chapter on village and provincial etiquette he speaks of certain scoundrels who ought to be stripped, and in Shakspearian phrase, be lashed naked through the world, by whips in the hands of honest men. Indeed, Mr. Banks! We should have thought that any the greatest breach of etiquette would have been punished enough and

\* *Medical Etiquette; or an essay upon the laws and regulations, which ought to govern the conduct of members of the medical profession in their relation to each other. Compiled exclusively for the profession. By Abraham Banks, Esq., M.R.C.S. &c. London, 1839. Small 8vo. pp. 104.*

to spare by an oblique whipping through the Russian Empire—say from Riga to Odessa, and that these tremendous Shakspearian lashings should be reserved for very black offenders. The fact is, that Mr. Banks constantly encroaches on the domain of medical ethics. Perhaps we ought not to blame him for this, as he gives some warning of his intention in the title-page; but we blame him for being angry so often, as he certainly diminishes thereby his powers of persuasion; and we wish he had not passed over so many points belonging to etiquette in the strictest sense of the word, from the belief that they were too trifling to deserve notice. Nevertheless, we thank him for his book, for it will draw attention to an important subject; Rome was not built in a day, and it was not fated that a code of medical etiquette should be constructed in the first foolscap octavo put forth upon the topic.

Let us now come to particulars, and with the assistance of Mr. Banks, let us discuss a few points of professional etiquette.

The first question mooted is, what is to be done with the fee, when one practitioner attends for another, particularly at a labour. The author thinks the fee should be halved, one part being given to the practitioner who was engaged to attend the case, and the other to the one who really did. We see no objection to this method; but we do not agree with Mr. Banks when he proposes that in this bipartition no fee is to be recognised below one guinea, or above two. He observes that some practitioners attend for nearly as few shillings as others do for guineas, and thinks it unfair that he who may have paid two or three guineas to his deputy should receive a crown or less, when in turn he is the substitute for his friend. But the truth is, that in proportion as the pay is higher, the qualifications demanded are higher likewise; so that if Titius,

being unable to go to a ten-guinea labour, chooses Caius as his deputy, he shows as plainly as actions can speak that in his opinion Caius is qualified to act as accoucheur in the houses of the more refined part of society; and these merits would be insufficiently rewarded by the half of two guineas, the highest fee recognized in the proposed scale. It is not very probable that when Caius in turn is unable to go to a ten-shilling labour, he will select Titius as his substitute; but if he did, it would be less mortification to the higher practitioner to attend a labour, once, for five shillings, than by the proposed arrangement it would be for the minor accoucheur to get only a tenth of the fee, instead of a half, merely because it was a good one. The next difficulty that Mr. Banks tries to smooth down is, that which arises when one general practitioner being already in attendance, another is called into consultation. In this case it sometimes happens that the second practitioner gives his advice gratuitously, which is not so pleasant as might be; and sometimes the second is paid like a physician, receiving his guinea, while the original attendant gets half-a-crown. The author thinks this "monstrously absurd" and unfair towards the first practitioner; "why," he asks, "should two men holding the same rank, possessing the same legal qualifications, the actual experience and knowledge pretty equally balanced, be placed in such different positions?" The obvious answer is, that the public do not much care for legal qualifications, and that the friends of the patient, when they call in the second practitioner, do not believe him to be on a level with the first one in acquirements, but infinitely superior. It would, no doubt, be much pleasanter for practitioner 1, if No. 2 had been a physician, or pure surgeon, as is the case ninety-nine times out of a hundred; but when, that single hundredth time, the second practitioner is of the same nominal rank

as the first, the sick man and his family consider him as essentially of a very different one; they do not look into any printed list for his name, but "read his glories in an outskirt's eyes!" Nay more, it may happen, says angry Mr. Banks, that the second practitioner may be the younger man of the two, but being in good circumstances, and practising as a physician, though not one by diploma, he is remunerated by fees; while his predecessor and fellow-attendant gets the amount of his draughts only. This he thinks "utterly farcical," and the sole remedy he can propose is, that the first practitioner is to require the same fee, and at the same time, that the second one receives it; "and this, too, whether that other be a regularly qualified physician, or simply practising as such, under the feigned title of surgeon." We fancy that Mr. Banks does not here mean what he says; and that by "a regularly qualified physician" he does not intend one practising solely as a physician, but rather a general practitioner who happens to have a diploma. But, in any case, his rule is a bad one, and almost impossible to put into practice. It would be much easier to insist upon it that the first practitioner should in every case have a vote in the choice of the second, as he generally has, in point of fact, than to stipulate for immediate guinea fees, when the family expected merely the usual charges at Christmas. This bill will certainly not pass into a law. Moreover, Mr. Banks "cannot resist the temptation of suggesting that years should be made the grand basis on which to found distinctions in the profession." But surely this is done already, to all reasonable amount. In no profession are grey hairs more respected than in ours. What more would any one wish? Why, Mr. Banks wishes, that as a certain age is requisite for examination at Blackfriars and Lincoln's Inn Fields, so, as men advance in years, they should be eligible for higher ho-

nours. We do not think that practitioners of a certain age would much thank our medical legislator for subjecting them to continual examinations; as life wears away, they are too happy to be allowed to let slip the class and order of digitalis, and the various methods of preparing tartar emetic; these, they say, are sweet forgetfulnesses, the *juvanda oblivia vitæ*! They would add, that by the time they have arrived at forty or so, the profession and the public have given or withheld their certificates of competency, their diplomas of talent, without any need of going up to another board of examiners; and as for a testimonial of age, nature stamps that on the face and gait in very legible characters.

Moreover, practitioners who are tired of the drudgery of the profession, and think themselves qualified for the highest walk, may throw aside pharmacy whenever they please. The degree of M.D. is no longer necessary, and the late regulations of the College of Physicians offer special indulgences to those practitioners who have attained the age of forty.

Mr. Banks does not like young M.D.s. He will have it, that the "fact of a young man leaving a University to practise as physician, to teach his grandmother the elements of life, is as ridiculous as it would be to make him a commander-in-chief of an army, or admiral of a fleet."

Not so: if the green M.D. were made President of the College, the cases would be analogous; as it is, the resemblance fails. Besides, we humbly conceive, that if a man has made good use of his time up to six-and-twenty (the youngest age for a physician recognized by the College) he may teach ancient ladies "the elements of life," or the elements of physic, without infringing on common sense, or medical etiquette.

Lack of space compels us to stop, but we shall resume the subject.

ON THE CEPHALIC GANGLION,  
COMMONLY CALLED THE PITUITARY GLAND,  
AND ON ITS CONNECTIONS WITH THE  
NERVOUS SYSTEM OF ORGANIC LIFE.

By M. BAZIN.

AFTER an historical account of the researches relating to the connections of the pituitary gland with the filaments of the sympathetic, the author passes to the facts which he has observed.

"The filaments by which the cephalic ganglion or pituitary gland is connected with the organic nervous system arise from the anterior and posterior aspects of the ganglion, from which they pass laterally to proceed immediately to the internal carotid artery, around which they wind, giving filaments to the carotid plexus. Several filaments thus anastomose with the net formed by the cavernous plexus.

The filaments arising from the anterior aspects of the cephalic ganglion, are the largest: they form a fasciculus two millimetres wide, which is produced by the union of the two principal trunks. Arrived at the internal carotid, in the level of the concavity of the curve which it makes to go to the brain, they form a small gangliiform plexus. A filament given off by the anterior trunk turns round the anterior and external aspect of the internal carotid, and divides into two filaments, each of which passes to one of the opposite extremities of the carotidian or cavernous ganglion. This ganglion furnishes several filaments, which pass to the third pair, and go to the ophthalmic ganglion. Behind, the cavernous ganglion sends several filaments to another ganglion situated between the external surface of the carotid, and the first branch of the trifacial. The last ganglion gives several filaments to the outer surface of the carotid; others go to unite with a plexus situated between the third pair and the ophthalmic branch of the fifth; and this plexus gives two filaments to the sixth pair. The others go backwards, to what appears to us to be a true ganglion, situated in the internal surface of this first branch of the trifacial. The ganglionic plexus resulting from the union of the nerves coming off anteriorly from the cephalic ganglion, sends two moderate sized filaments over the concavity of the last curve of the internal carotid, which are connected on the one hand with the *nervi molles* of the cavernous plexus, and on the other with the large filament which the superior cervical ganglion sends under the lower and outer surface of the internal carotid. Other filaments proceeding from the anterior surface of the cephalic

ganglion, and others still which arise on its posterior aspect, embrace, and twine round the carotid, and are also continued to the filament we have just pointed out.

I have discovered the same relations, only less complicated, between the cephalic ganglion (pituitary gland) and the superior cervical ganglion, in the eagle and the ostrich.—*Comptes-Rendus*, Oct. 21, 1839.

#### HINT TO CERTAIN CANDIDATES.

As a hint which may save our canvassing friends at the "Middlesex" some trouble, and perhaps turn their efforts into another channel, we have now to state, what we have for some time suspected—namely, that neither Dr. Watson nor Mr. Arnott intend to accept office in King's College Hospital.

## LECTURES

ON THE

### PRINCIPLES AND PRACTICE OF SURGERY.

*Delivered at the Westminster Hospital School,*

By BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

## SUPPURATION.

**ABSCCESS** *continued.*—*Treatment*—*General remarks*—*Acute*—*Chronic*—*Incision*—*Caustic*  
—*Seton*—*Trepan*—*Emetics*.

**FISTULA.**—*Definition*—*Cause*—*Formation*—  
*Diagnosis*—*Pathological anatomy of*—*Treatment*.

**HECTIC FEVER.**—*Nature*—*Treatment*.

*Treatment.*—Abscesses may be absorbed; we have abundant evidence of this fact. It is important to ascertain under what circumstances this phenomenon has happened, as we may be enabled to excite, artificially, a similar condition in the economy, and in this way obtain similar results. They have disappeared apparently under the influence of a profuse diarrhoea, suddenly occurring, of a profuse perspiration, and of other analogous secretions. Under the influence of one or other of these conditions this desirable conclusion will now and then happen; the pains of spontaneous or artificial opening, the dangers of profuse suppuration, are spared, and with these the avoidance of a deformity in the shape of a cicatrix, are matters of great importance. What nature has thus occasionally done, art has endeavoured, with some success, to imitate; drastic purgatives, diuretics, and sudorifics, have been exhibited with the same intent. Certain local applications are also employed for the same purpose: stimulating frictions, blisters, or pressure, will occasionally suc-

ceed where the disease is inactive. These means are rarely of any use in acute abscess, which usually runs its course to opening. If the parietes of a chronic abscess be thick and highly organized, we shall rarely succeed in removing it by these remedies. Those upon which we sometimes act with success are such as appear suddenly, and without very decided inflammatory action, and in exhausted or scrofulous subjects. But to obtain this desirable object much caution is required; if the gastro-intestinal system be already irritable, it would be clearly unwise to exhibit drastic purgatives, or we should probably render matters worse. Under almost any circumstances it is a system which, if it do not succeed, may make the patient's condition worse than it was before; in fact, it is a "double or quits" practice, which should only be used with much reserve. If the first efforts upon the stomach and bowels, the kidneys or skin, are without effect on the tumor, and more especially if the stomach appear unlikely to support their action, they should be abandoned. Stimulant local applications will sometimes succeed, when the inflammatory action is slight. Iodine, mercurial frictions, and blisters, will sometimes succeed in procuring absorption; at the same time you must bear in mind that they will sometimes excite inflammatory action, where it did not before exist, and their use must, therefore, be carefully watched. The safest plan in the great majority of instances is the antiphlogistic; for to a certain extent inflammatory action is always present in these cases; but this mode of treatment must not be pushed beyond the point necessary to keep that action within moderate limits, otherwise it may prolong the disease almost indefinitely. If the patient be vigorous, and the action at the part considerable, the tumefaction, heat, pain, and redness, great, purging and local blood letting, with emollient applications, will

be decidedly useful; but when these symptoms subside, this treatment, with the exception of the emollient, to soften the integument, is no longer necessary. There can be no doubt that increased irritation at the part is accompanied by increased exhalation; excite a serous or mucous membrane, and its proper secretion is soon increased; stimulate an abscess, and you will soon see the same effect produced. Lessen irritation and as surely you will find the redness, the heat, and the induration disappear; its bulk will seem to lessen, probably in consequence of increased facility for absorption being afforded. Therefore, so long as any very manifest irritation exists at the part, antiphlogistic means are clearly indicated.

When abscesses have arrived at a period when the evacuation of their contents has become desirable, there are various modes by which it may be accomplished.

*Acute abscesses.*—Before we proceed to speak of opening such abscesses there are certain indications to be attended to; it is necessary to lessen inflammatory action at the part, by antiphlogistic means, before suppuration is established, because it may be sometimes prevented; the means to be employed are blood letting, cold, purging, and diet. When the formation of abscess seems to be inevitable, we should employ the antiphlogistic treatment, associated with relaxing applications, for the purpose of reducing the surrounding inflammatory action. But these means, good in themselves, may be carried too far; the tension and pain may disappear, nature seems exhausted at the part, suppuration appears to languish, and the disease is almost indefinitely prolonged; therefore, such means must be employed with care. Usually, before we open these abscesses we should be satisfied that pus is fully formed and fluctuation manifest; but as I have already stated there are many exceptions to this rule, there are many which must be opened early; those, for instance, which are accompanied by excessive pain; whitlow; those under aponeurosis, the palm of the hand, the sole of the foot; those in the axilla, and near the anus, and other parts where the cellular tissue is abundant and lax, through which the pus may be infiltrated; those in the midst of tendons; those nearly connected with bone, or a consequence of diseased bones, because in their progress they may cause a bone to be extensively denuded. Weidmann thought that the pressure exercised upon a bone by confined pus might occasion necrosis; those abscesses which, without being very large, interfere with the functions of important organs, the pharynx, the fauces, and other parts of the neck and throat; lastly, those nearly

related with some important cavity, the thorax, the abdomen, or large articulations; into one or other of these cavities pus may, though very rarely, find its way. But although it very rarely happens, what good is to be got by running a risk so easily avoided? The son of the celebrated Petit had an abscess in the axilla, yet the pus found its way into the chest; many other analogous facts are on record. Some persons think that abscesses developed in the course of large arteries should be early opened, because the pus may perforate the arteries, and cause hemorrhage. Although it may be well to open such abscesses early, the reason given for it is not a good one; pus on the outside of an artery may irritate and excite inflammation in the parietes of the artery, but the blood within will be coagulated, so that even if perforation occur, it need usually excite no fears of hemorrhage; there are yet other abscesses requiring early opening, produced by the infiltration of irritating fluids, the urine, or any other; these must be opened as soon as discovered, by incisions proportioned to their extent.

The mode of opening abscesses, however, is a matter of much importance, because each mode is best adapted to peculiar cases. The use of each should therefore be governed by particular rules. The two principal modes are *incision* and *caustic*, but there are others that are occasionally employed.

A cutting instrument should be employed to open acute or phlegmonous abscess, because as soon as you determine to open it, no time should be lost in effecting the object. M. A. Petit, who had a great horror of admitting air into these cavities, recommended that they should be opened with a red hot stilette or needle, and that the fluid should be extracted by means of cupping glasses. He very warmly recommended this mode of opening abscesses, urging that the cavity was very rapidly filled up. Whether this be the case or not I am unable to state, for in the practice of the present day this plan is excluded; and if the suggestion had any value, the object might be better attained by placing glasses over a very fine trochar canula.

I have already stated my reasons for believing that the knife is best adapted to acute or phlegmonous abscess; but it may be and is very largely employed in the treatment of chronic abscess. Usually it is a simple, sometimes a difficult operation. The kind of instrument, the number of incisions, the time of repetition, are not unimportant matters. I prefer the bistoury to the abscess lancet, because we have more command over it; if the abscess be small, or the person timid, a common lancet may, of course, be employed.

The bistoury I use is a double-edged one, which makes an opening of any extent, not less than that of an ordinary lancet. If any doubt exist, or the abscess be deep-seated, it is best gradually to cut upon it, rather than plunge an instrument into it at once; and if it be very obscure, it may be as well first to puncture with an exploring or grooved needle. The same course should be taken if the abscess be nearly connected with a large cavity, if it be nearly related to an artery of some magnitude, or other important organ. Those abscesses consequent upon urinary extravasation also require incisions in the perineum early and carefully made. If there be no counter-indication, we must consider the sufferings of the patient, and therefore we usually plunge the instrument at once into the sac of the abscess; but once arrived there, in many cases it is necessary to enlarge the incision. In these cases the handle of the instrument is depressed, the edge is brought in contact with the tissues, and the opening is made of the required extent. In the greater number of cases a single opening is enough, but cases occur in which more are necessary. The extent of the incision must depend upon the depth to be cut through: if it be great, the incision should be as much more extended, because the fluid does not so easily escape, and the parts cut through have often a strong tendency to unite. As a general rule, the direction of the incision should correspond with the axis of the body. In those abscesses situated under muscles, which it is necessary to cut through for the purpose of liberating the pus, it is clearly not advisable to cut transversely through the fibres, because it is sometimes inconvenient; sometimes, however, it is necessary to cut transversely through the fibres of even a strong muscle, if any sufficient object be gained by it—when an abscess is under the pectoral, for instance. We have stated that a single incision is usually sufficient, but occasionally more may be required. An abscess may present several distinct cells. In very large abscesses, several incisions will often do better than one, for in the present day we are indisposed to make an incision extending from the trochanter to the heel, such as was often made in the last century. Neither in the present day, when an incision is made, do we introduce the finger for the purpose of breaking down any septa or bands which may extend across the cavity; these bands are often blood-vessels and nerves, which resist destruction for a longer time than cellular tissue. In this case, the least inconvenience the patient sustains is considerable pain. The only justifiable reason

for introducing the finger is to ascertain whether the incision be large enough.

In those abscesses depending upon sub-acute inflammation of lymphatic glands, I have very rarely found blood-letting or cold, however far pushed, restrain their development; the only successful means I know of treating these abscesses, is repeated blistering, with pressure as soon as it can be safely borne. The ordinary antiphlogistic treatment will make them sluggish, will interfere with the circumscription, and will rarely arrest their progress.

*Chronic abscess.*—Arrived at maturity, these abscesses must be treated differently from those which are more acute in their character; for instance, as a rule, a chronic abscess should never be allowed to open spontaneously; at the same time it is not a matter of urgency to open them as soon as they are discovered. When they are opened, I have stated that two means of accomplishing this object are presented—caustic and the knife. If we employ the former, I would recommend you to use a paste, made by mixing together six parts of caustic potash and five of quicklime in fine powder, to which as much spirit of wine as may be necessary to make it into a paste is added. Of this paste a piece of the desired size and form is applied upon the centre of the tumor. In from five to fifteen minutes a slough of the necessary thickness may be obtained; and within ten minutes, usually, the whole thickness of the cutaneous integuments is destroyed. The object of using the caustic is to irritate the parietes of the abscess, and thus to increase the tendency to obliterate the cavity. If the abscess be of great extent, such an application, and the development of inflammation over so large a surface, would be clearly imprudent; and in those cases repeated punctures are preferable, repeating them when the accumulation is much less than on the first occasion, and immediately closing the opening. By this means the cavity is often so reduced as to allow ultimately of the use of the caustic. A first application of caustic is often insufficient; a second, or even a third, is sometimes necessary. With regard to the successive punctures, I have one observation to make: although a first, a second, and a third, may heal, it will happen that one will ulcerate and establish a fistulous communication.

Some persons, and among them Benjamin Bell, advocate the use of the *seton*. If the object be to procure a gradual discharge of the pus, it is attained by this means; but if it be also supposed that air will be excluded, this is an error; for

in a few days the seton orifices will be sufficiently enlarged to admit any quantity of atmospheric air, and the irritation which it excites is sometimes of serious inconvenience.

In order completely to exclude atmospheric air from the cavity of an abscess, the opening should not be very large; it should be made with a narrow bistoury, just large enough to allow the pus to pass in a continued stream. The moment it ceases to do so, the lips of the wound should be brought together, and carefully secured by means of adhesive plaster. It may be necessary again and again to repeat it, the time varying with the rapidity of the secretion. Before it is done the tumor should be tense, and the fluid compressed. If at this time the collection be smaller than before the first puncture, we have the satisfaction of knowing that the surrounding tissues are acquiring their natural elasticity, and that the exhalation is less abundant.

Whatever mode of opening may have been employed, certain general principles of treatment must be employed, except in the cases to which I have last alluded. The dressings should be so managed as to insure the gradual evacuation of the pus, and as much as possible to bring together the parietes. If the incision tend to heal up, a dossil of lint should be interposed to prevent it; at the same time full liberty of escape should be afforded for the pus, otherwise the parietes would be again distended. When the opening does not correspond with the most depending part of an abscess, the pus may go on accumulating, may be acted on by the atmospheric air, become decomposed, and be a source of great irritation. It is always prudent, therefore, when the opening is not at the most depending part, to endeavour, by position, or compression, to give the part such a bearing as will enable the pus to flow towards that point. Compression will rarely succeed unless associated with position: both may fail, and counter-opening is the only course to pursue.

There are a few cases where the use of the trepan is necessary to procure the evacuation of abscesses; those of the interior of the cranium, when well made out, may require it; those of the anterior mediastinum may require the application of the trepan upon the sternum. But abscesses in that region are not easily made out: there should be pointing. In such a case, the object in perforating the sternum is to give the pus a more direct channel for escape than it might have if a puncture were made where pointing is seen. Where abscesses exist in bone, the application of

the trepan is again indicated. David, in France, and Sir Benjamin Brodie, in our own country, have done much to simplify abscesses of bone. In David's memoir, crowned in 1764, we find the following statement:—"Bones are susceptible of inflammation and tumor of their substance; these tumors may terminate by a species of suppuration which is proper to bone. If the progress be slow, the pain will not be very acute; but if it be rapid, the pain will be very great." After pointing out many dangers which attend upon them, he says, "All these considerations make us feel the necessity of promptly opening such abscesses, and still more the necessity of distinguishing them. It is very difficult to establish the existence of abscess in the substance of a bone, especially when there is no considerable external tumefaction. The symptoms upon which we can most surely rely are, a heavy dull pain in the bone, which becomes more and more severe, confining itself very much to the point where it was first felt; an external œdema; the pain becomes more gnawing; there is sleeplessness, irregular rigors, fever," &c. After pointing out the necessity of early opening, he says, "When it exists in a bone sufficiently large to admit of it, the tibia, the sternum, &c. the treatment must be, to apply a crown of a trepan upon the point where the abscess exists. If the bone be thinned, and give way under the trepan, we may use a strong scissars or other instrument." Sir B. Brodie's able paper is contained in the *Medico-Chirurgical Transactions*.

*Emetics.*—There are certain situations in which emetics may be used as a means of evacuating abscesses; those of the pharynx and its vicinity are among those in which this means is often successful. During the efforts of vomiting all those parts are violently stimulated, convulsive movement affects them, their surfaces rub one against another, and the abscess may thus be broken. Instantaneous relief is experienced, and the cure is usually rapid. We should not, however, have recourse to them indiscriminately; they are only applicable to abscesses about the organs of deglutition: if an abscess in this organ be large, it is often impossible to open the mouth sufficiently to use cutting instruments, and here this means has a peculiar value. Emetics should not, however, be used if the stomach be very irritable; but in the absence of all symptoms of gastric irritation, emetics prudently administered, and carefully watched, may often be used in these cases with much advantage.

#### FISTULA.

An abscess may not completely heal

after incision, a discharge may continue, and a fistulous canal may be the result. By a *fistula* we understand an accidental canal, destined to give vent to liquids naturally or accidentally formed; these canals may open upon the cutaneous or mucous surfaces, sometimes upon serous or synovial ones.

Among the causes capable of producing fistula is very considerable destruction of cellular tissue under the skin, so that the cutaneous integument does not come in contact with the deeper tissues. This may be a consequence of abscesses whose walls have not come together; chronic inflammation of lymphatic glands—in the neck, the axilla, or the groin; chronic ulceration of joints, occasioning abscesses opening externally, caries and necrosis; foreign substances in the tissues of the body; perforation of certain reservoirs or canals destined to contain or carry away excrementitious matter—such as bile, saliva, urine, &c.

It is easy to understand how an abscess which has denuded the cutaneous integuments produces fistula: the parts cannot be brought together to adhere; the accidental surfaces must still remain; the purulent secretion from those surfaces continues to be formed, and must have vent, and the opening is thus perpetuated. So in the case of a foreign body; it keeps up the irritation which its presence at first excited; pus continues to be secreted, and must be poured out; therefore the opening remains. These are usually the least important cases of fistula; those which communicate with reservoirs or canals are much more troublesome, much less manageable. Whether communicating with the stomach, the lungs, or with any excrementitious canal, they succeed to wounds or inflammation of those several parts. Generally, when connected with excretory canals, they irritate and tumefy the mucous coat of those canals, and materially lessen their calibre. They thus interfere with the passage of the fluids which they usually carry, and the accumulation of the fluid behind the contracted point not unfrequently distends and irritates the part so as to occasion a new abscess: this in time opens; the fluids pass through it, and a second fistulous canal is the consequence: thus we often find several at the same time in the neighbourhood of the anus and the urethra. They may be produced by a foreign body, a calculus, for instance, lodged in the urethra; a fish-bone, or other body, in the rectum. Where an excretory canal is surrounded by much cellular tissue, another circumstance not unfrequently happens: the canal is inflamed, the cellular structure external to it is inflamed also; abscess is formed, and

discharged perhaps externally, and at the same time, or subsequently, the parietes of the canal give way, and what is usually termed a complete fistula is the consequence. These are seen only in the neighbourhood of the urethra, the rectum, and the lachrymal duct.

Much difficulty is not usually experienced in detecting a fistula. Whenever after a wound or an abscess we find the opening contracting, without completely closing, still furnishing a larger quantity of pus than its apparent extent would seem to explain, we may presume that a fistula exists. Two principal circumstances serve to distinguish, at the first blush, fistulas from other lesions of the soft parts: the first is based upon the aspect of the part; the second upon the character and quantity of the fluid which it furnishes. Almost all fistulae present a contracted orifice, sometimes depressed, sometimes presenting a puckered appearance not unlike a miniature sphincter. Sometimes the orifice is red, fungous, and projecting. Often the surrounding parts are solidified by the permanent irritation at the part; they become callous, and the callous masses are sometimes so considerable as to form projecting, and sometimes horny tubercles, which it is necessary to excise; all means employed in the hope of softening them being useless. The character of the fluid gives more certainty to the diagnosis. Thus when a wound, whatever may be its dimensions, furnishes a larger quantity of fluid than is proportioned to its extent, we must suspect that behind it a fistulous canal exists. This presumption acquires greater probability when the matter is sanious, greyish, or exhales a faint or fœtid odour, offering the characters of pus furnished by carious bones, or those of fibrous or glandular tissues. This probability becomes a certainty when liquids are poured out which under ordinary circumstances are carried along certain excretory canals—saliva, tears, bile, fecal matter, urine. But we must not rest satisfied with the discovery that a fistula exists: we must, as nearly as may be, ascertain its extent, its direction, its connection with important organs; whether it be connected with caries or necrosis, with perforations of certain organs or certain canals; otherwise it will be impossible to employ with success those, sometimes delicate, operations which are required for their cure. It is rare that the fingers can be used to explore: it is therefore necessary to have recourse to probes or sounds. Care should be taken to remove all obstacles to the passage of the exploring instrument: it should be passed along with great care and gentleness, rather letting it find its own way

than using any force in directing it, and carefully observing the direction it takes; and if the communication be with an excretory canal, at what point it joins it. There are some fistulous canals connected with excretory channels, whose point of communication is pretty uniformly situated at one point; those of the rectum or anus, for instance; but in the greater number of cases no such rule obtains. How is it that fistulous canals so obstinately resist attempts to obliterate them? Simply because they are invested by a membrane the opposed surfaces of which have an invincible repugnance to enter into adhesion.

*Pathological anatomy* shows us in all fistulæ a principle which is a foreign body, a caries, a necrosis, a cavity whose parietes are ill organized; a large cavity, the chest, the frontal or maxillary sinus, the larynx, &c.; a canal of variable length, from some lines to some inches, sometimes sinuous, formed by a tissue sometimes very hard, callous, sometimes only slightly so; and an orifice through which the fluid is discharged, which is sometimes depressed, sometimes projecting, narrower than the canal which it terminates. At the first period of the existence of a fistula the adjoining parts are inflamed to some distance; the walls of the fistulæ are covered with granulations, which, if the source of irritation be removed, will speedily close the canal; but if this period be passed, they become lined with a mucous-like tissue, which acquires a power of resistance and permanency, independent of the cause which has produced the fistula. This tissue by which a fistula is lined is at first presented in the form of granulations, and then the canal is placed under circumstances most favourable for cure; but the continual passage of fluid along it soon changes its character, and a reddish villous membrane, having apparently all the characters of mucous membranes, is the consequence; as if nature, in case of disease, resorted to the original plan of organization. It is along mucous surfaces that all excrementitious matters pass. If a fluid be accidentally secreted, or if a fluid ordinarily carried along natural channels accidentally opens for itself a new course, if this new channel persist for a certain time, it assumes all the characters of the natural channel. The analogy of this membrane with the mucous tissue has been contested by some persons: whether right or wrong in this, so much is certain, that like the mucous tissues it is provided with a very delicate capillary tissue, that it presents the same appearances, and answers the same purpose. It is true that, so far as I know, no follicles have been demonstrated,

neither have they in many portions of the mucous tissues. The sensibility of this tissue is obscure under ordinary circumstances, but capable of being greatly exalted under the influence of irritation: it is the seat of a tolerably active exhalation and absorption. Its principal use appears to be to protect adjoining parts from contact with the irritating fluids which frequently pass along them. When strongly or frequently irritated it may become very thick, callous, and almost insensible. Nearly always, fistulæ around their external orifice present more or less thickening, and if the fluid passing through them be very irritating the whole length of the fistulous canal feels like a knotted cord.

Fistulous canals furnish fluids which are mixed with those which are conveyed from within: the characters of those fluids vary with the quantity of inflammation and the duration of the living tissue. When recent, the fluid is purulent; if inflammatory action be intense it may be bloody: it may be fetid, and capable of excoriating the skin. When they are old, and not much inflamed, the fluid is viscid, whitish, almost transparent, inodorous, presenting the ordinary characters of thin mucus. The gravity of these affections varies with the producing cause, with the organs whose functions they derange, and with the facility with which art can provide a remedy. Next to these circumstances are the particular condition of the case, the seat and number of the orifices, the density of the irritated structures along which they pass. There are some which sap all our comforts, or even threaten life—artificial anus, urinary fistulæ; others which are a lasting inconvenience—salivary fistulæ.

Left to themselves their course may be different. Some will now and then cicatrize, though the cause which has produced them still exists; but then inflammation, abscess, and a new fistula, are the consequence: this may happen again and again, until a large irregular mass, almost to the touch like scirrhus, is the consequence. When fistulæ are thus deep, large, and numerous, and furnish much pus, they gradually bring about emaciation and general prostration. The cellular tissue becomes infiltrated, and hectic and death may be the consequence.

*Treatment.*—All fistulæ are not susceptible of cure; some are incurable, because we cannot destroy the cause which keeps them up, or because they are connected with organic mischief of too serious a character to admit of removal. There are some in which it might be possible to bring about cicatrization, but it may be dangerous to do so: probably those occurring by the sides of the anus of persons

suffering from phthisis are in this class. In these cases we do no more than counsel methodical dressing, remove, as much as may be, all irritation, and see that no obstacle to the passage of fluids is developed.

In the methodical treatment of fistulæ, certain leading principles must be borne in mind; we must be satisfied as to their origin; we must seek to relieve the condition which has given birth to them; the treatment must, therefore, be very variable. This *primum mobile* being destroyed the indurations around the fistulous canal will often soften down of themselves, without the necessity of carrying, as the ancients did, the knife and the fire into the treatment. This does not, however, always happen; those indurations are sometimes so considerable that absorbent action is insufficient for their removal. If the fistulæ succeed to abscesses, which have much thinned the integument, destroying the cellular tissue and the nutrient vessels; compression carefully applied, so as gently to bring that integument in contact with the deeper tissue, will sometimes cause them to adhere. Stimulating injections, by exciting a more acute degree of inflammation, will sometimes produce a similar effect. If these means fail it will be necessary to apply the actual or other cautery to lay open the denuded integuments, or even to excise it with a scissars, or destroy it with caustic. When considerable abscesses exist in situations where little tendency exists to bring the sides together, so as to adhere or contract, such as the axilla, the neighbourhood of the anus, and so on, we must take care that they are kept clean, and take means for restoring the general health; the tissues then will tend to fill spaces produced by emaciation, and tend to obliterate the cavities so produced. Without this species of organic reparation, injections, and even incisions, will often fail in curing the disease. Some fistulæ happen in consequence of the fundus of an abscess being much more depending than the opening; the purulent matter accumulates, and the disease is maintained. In such cases we must recur to nicely adapted compression; that failing, we must employ counter-openings. When abscesses of lymphatic glands terminate in imperfect suppuration, fistulæ are not uncommon. It is necessary, then, to destroy the glandular irritation, which is often conveniently done by blisters applied in the neighbourhood, and the fistulous canal will soon yield. Where they are occasioned by carious or necrosed bones the cure is difficult, and in general very tedious, because we have no very certain means of accelerating or arresting the progress of one or the other; therefore, until these diseases are dissipated,

the direct treatment of the fistula cannot be employed. Where there are many tortuous canals communicating with an organ at one or many points, it is sometimes advisable, before recurring to the principal operation, to perform minor operations for the cure of these complications, to lay open those several canals or sinuses into one principal one, as this course will often lessen surrounding induration, and make the way smoother for the latter operation. In fact, we cannot resort to the radical cure without inconvenience until these preliminary matters have been disposed of. There is one cause of fistulæ after abscesses which is rarely sufficiently attended to—motion. Wherever motion is considerable, there an opening of an abscess shews less tendency to cicatrize. John Bell relates a case of fistula in the axilla, which resisted apparently the best directed means of treatment for a long time. During its existence the patient fractured his arm; it was necessary to keep the arm fixed to the side for some weeks, and the fistula was cured.

Particular fistulæ we shall describe with the diseases of particular organs.

#### HECTIC FEVER.

Profuse or long-continued suppuration may end in the production of hectic fever. John Hunter thought it indicated "a constitution now become affected with a local disease or irritation which the constitution is conscious of, and of which it cannot relieve itself, and cannot cure." He thought "we should distinguish between a hectic arising from a local complaint entirely, where the constitution is good, but only disturbed by too great an irritation, and an hectic arising principally from the badness of the constitution, which does not dispose the parts for a healing state; for in the first, it is only necessary to remove the part (if it be removable), and then all will do well; but in the other we gain nothing by a removal, except the wound made by the operation is much less, and much more easily put into a local method of cure."

The term *hectic*, we apply "to a continued febrile movement, of uncertain duration." It is most commonly a consequence of slow profound suppuration. It is characterized by general paleness, accompanied, with more or less constancy, by a circumscribed redness of the cheeks, emaciation, flabbiness of the flesh: these are the more striking features of persons in whom hectic fever has been some time developed. Even at this period the digestive functions are often satisfactorily performed; the appetite continues, or is even increased, but the patient always complains of heat and dryness of the fances,

and of considerable thirst; the pulse is hard and frequent, especially towards evening and after the lightest meal. The respiration is rapid and hurried on the slightest exertion; at a later stage of the disease it becomes more distressing. There is often a short dry cough, particularly after taking food, although the respiratory organs are not the seat of any primary disease. The general heat is increased, the skin is dry and hard, and this is generally felt by the patient at the palms of the hands; the eyes are brilliant and humid; the cheeks, over the malar bones, red. At first, cutaneous transpiration is suppressed, but at a more advanced period of the disease the perspiration is abundant, though unequal, affecting particularly the head, the neck, the chest, and epigastrium; increasing at night, and especially towards morning. The urine is frequently scanty, high-coloured, and deposits a whitish or reddish sediment. To the constipation which was the characteristic of the earlier period, succeeds, sooner or later, a diarrhœa, which soon becomes colliquative, and rapidly breaks down the remaining strength of the patient. Emaciation then proceeds with greater strides; the legs become œdematous, the temples hollowed, the eyes sunken, the muscular power exhausted; the hair drops off, the nails are curled and livid, sleep is interrupted by constant dreams—it is no longer a relief or a work of reparation. The lassitude is very intense, but, strange to say, during this general lassitude, the genital organs are extremely active. This gradual wearing out of all the physical faculties is strangely contrasted with the integrity of the intellectual faculties up to the hour of death.

Hectic usually presents a continued type, with exacerbations; not unfrequently the remittent type, or quotidian or double tertian; very rarely intermittent, the patient seldom being without fever in the intervals. The paroxysms are commonly observed in the evening; sometimes there are two in twenty-four hours. The duration of this fever is generally long and undetermined; it ends commonly only with life. It generally brings about, by the gradual extinction of the vital powers, a quiet, easy, unexpected death, whose approach is usually concealed by an agreeable veil of hopes and illusions.

The hectic, says Hunter, comes on at very different periods after the inflammation and commencement of suppuration, owing to a variety of circumstances. First, some constitutions fall much more easily into this state than others, having less power of resistance. The quantity of incurable disease must be such as can affect the constitution; and in whatever

situation or whatever parts, it will be always as to the quantity of disease in those situations or parts in the constitution which will make the time to vary very considerably. In many diseases it would appear, from the manner of coming on, that they retard the commencement of the hectic; such as lumbar abscesses: but when such abscesses are put into that state in which the constitution is to make its efforts towards a cure, but is not equal to the task, then the hectic commences. It will come on as much sooner as the parts affected are "more vital." Parts well disposed to take on such specific diseases as are not readily cured in any situation—the larger joints. In the small joints, although the same local effects take place, yet the constitution is not made sensible of it; we therefore find a scrofulous joint of a toe or finger going on for years without affecting the constitution. The ankle, wrist, elbow, and even the shoulder, may be affected much longer than either the knee, the hip-joint, or loins, before the constitution sympathises with their want of powers to heal. "Although the hectic commonly arises from some incurable local disease of a vital part, or of a common part when of some magnitude, yet it is possible for it to be an original disease in the constitution;—the constitution may fall into the same mode of action without any local cause whatever, at least that we know of." In this opinion I do not coincide. "Hectic may be said to be a slow mode of dissolution: the general symptoms are those of a low or slow fever, attended with weakness, but more with the action of weakness than real weakness; for upon the removal of the hectic cause, the action of strength is immediately produced, as well as every natural function, however much it was decreased before. "The disease has been, and still is, generally laid to the charge of the absorption of pus into the constitution from a sore; but I have long imagined that an absorption of pus has been too much blamed as the cause of many of the bad symptoms which frequently attack people who have sores."—"If this absorption of matter always produced such symptoms, I do not see how any patient who has a large sore could possibly escape this disease; because we have, as yet, no reason to suppose that any one sore has more power of absorption than another. If, in those cases where there is a hectic constitution, the absorption is really greater than when the habit is healthy, it will be difficult to determine whether the increase of absorption is a cause or an effect. If it be a cause, it must arise from a particular disposition in the sore to absorb more at one time than common, even while

it was in a healthy state; for the sore must be healthy and then absorb, which hurts the constitution: moreover, as the sore is a part of that constitution, it must of course be affected in turn; and what reason we have to suppose that a healthy sore of a healthy constitution should begin to absorb more at one time than another, I must own I cannot discover. If this increase of absorption does not depend upon the nature of the sore, it must then take its rise from the constitution; and if so, there is then a peculiarity in the constitution, so that the whole of the symptoms cannot arise entirely from the absorption of matter as a cause, but must depend on a peculiar constitution and absorption combined. If absorption of matter produced such violent effects as are commonly ascribed to it (which, indeed, are never of the inflammatory kind, but of the hectic), why does not the venereal matter do the same? We often know that absorption is going on by the progress of buboes; and I have known a large bubo, which was first ready to break, absorbed from a few days' sickness at sea, while the person continued at sea for twenty-four days after: yet, in such cases, no symptoms appear till the matter begins to have its specific effects; and these very symptoms are not similar to those which are called hectic. From reasoning, we ought to expect that the venereal matter would act with greater violence than the common matter from a healthy sore. Although matter, too, is frequently formed on the inside of the veins in cases of inflammation of their cavities, and this matter cannot fail of getting into the circulation, yet in these cases we have not the hectic disposition, but only the inflammatory, and sometimes death. We likewise find very large collections of matter which have been produced without visible inflammation; such as many of the scrofulous kind, and which are wholly absorbed, even in a very short time, yet no bad symptoms follow. We may, therefore, from hence conclude, that the absorption of pus from a sore into the circulation cannot be a cause of so much mischief as is generally supposed: and if it was owing to matter in the constitution, I do not see how these symptoms could ever cease till suppuration ceased; which does not readily happen in such constitutions, their sores being tedious in healing. "We find, however, that such patients often get well of the hectic before suppuration ceases, even when no medicine was given; and in the case of veins there is great reason to believe, that after all the bad symptoms are removed, suppuration is still going on, as we find it so in a sore: pus may, therefore, still pass into the constitution from the veins, and yet the hectic

may not be produced, which would certainly be the case if those bad symptoms were occasioned by the matter getting into the circulation." And I very much doubt the fact of absorption going on more in one sore than another; and if ever it does, I think it is of no consequence. I am much more inclined to believe that this hectic disposition arises from the effect which irritation of a vital organ and some other parts, such as joints (being either incurable in themselves or being so to the constitution for a time), have on the constitution.

Indeed the existence of suppurative action at all is not necessary to the production of hectic. Although I am not disposed to admit the many causes mentioned by Truka, because I believe he confounded many diseases under this denomination, yet I think that many cases of irritation or chronic inflammation of mucous tissues are capable of exciting it. It has also been produced by profuse pyalism, diabetes, sexual abuses, nymphomania: the existence of foreign bodies in the trachea has also occasioned it. It has ceased upon their removal. However, although these cases are sufficient to shew that the absorption of purulent matter is, at all events, not always the exciting cause, yet it is in cases attended by suppurative action that hectic is most commonly seen. I differ from Mr. Hunter in this, that I do not believe hectic to be an essential disease: it is, I apprehend, always a symptomatic disease, and every day's experience serves to make this more evident. In fact it may be regarded as the symptom of a chronic irritation, most commonly seated in some vital organ; and this organ explains its gravity.

The course of hectic may be divided into three periods. In the first, the only symptom which marks its existence is a slight febrile action; increased heat, appearing in the evening and ending towards morning. In the second, the febrile action becomes continuous. It is not until the third period that perspiration, colliquative diarrhoea, exhausted powers, marasmus, and œdema of the lower extremities, are ordinarily presented. Of all these mortal symptoms, the diarrhoea, which is usually regarded as most characteristic and most fatal, is not so indispensable as is usually believed, and presents much variety, dependent upon the state of the intestinal tube and the diet of the patient. Many phthisical patients will terminate their career with constipation—others, after having experienced slight diarrhoea for a few days. This condition is more frequently witnessed in hospitals, where patients in the last stage of hectic are carefully dieted, than among private patients, who are

often allowed to take whatever their capricious appetites may point out.

*Treatment.*—Unless we can remove that local disease of which hectic is a symptom, we cannot hope to cure this disease. To give bark and wine to relieve the debility which is so distressing a symptom when hectic is present, in many cases will be only to increase the local disease and to accelerate the fatal termination. Yet the surgeon often feels, in those cases where the disease by which hectic is excited does not affect a vital organ, that he is justified in exhibiting stimuli, for the purpose of giving the vital functions more power to resist the baneful influence upon the constitution, of the local disease. Thus in a disease of the knee-joint, ulceration with abscess, which so affected the system as to develop hectic, we are justified in exhibiting bark, wine, opium, camphor, &c.; which not only increase the power of resistance, but often seem to exercise a salutary influence upon the local disease. If, instead of this, hectic depended upon disease of the more important viscera, the exhibition of such substances would be most objectionable; they would increase fever and diarrhoea: in fact, they would increase all the patient's sufferings, and hasten the fatal termination.

Whether antiseptics, salines, with mineral acids, have so decided an action in lessening suppurative action as some persons believe, is at least very doubtful. Those persons who believe that hectic symptoms are often excited by the absorption of pus and its presence in the blood; (and the observations of Mr. Gulliver, to which I have already sufficiently referred, if confirmed, would increase that number), believing also that salines and acids would tend to change or destroy it, would naturally expect much good from the employment of those remedies. The only good I have ever seen derived from their use in such cases, is to lessen the profuseness of the perspiration, which is a source of so much distress to the patient.

If the hectic depend upon a local disease which can be removed (and this is often the case in the practice of surgery), we may at once cut short the progress of hectic. The disease may be an incurable disease of a joint: we can remove the limb, the constitution may at once rally when the source of irritation is removed, and all symptoms of hectic be dissipated. Hunter has known a hectic pulse at one hundred and twenty, sink to ninety in a few hours, upon the removal of the hectic cause. He has known persons sleep sound the first night without an opiate, who had not slept tolerably for weeks before; he has known cold sweats stop immediately, as well as those called colliquative; he has

known a purging immediately stop upon the removal of the hectic cause, and the urine drop its sediment: and this is the general experience.

## ON SYPHILIS.

By HERBERT MAYO, F.R.S.

Senior Surgeon to Middlesex Hospital.

[Continued from page 353.]

[For the London Medical Gazette.]

*Syphilitic psoriasis continued—Syphilitic lichen—Group of symptoms in the lichenous form of secondary syphilis—Treatment—Cases—Ulcerative affections of the skin—Lepra—Tubercle—Ecthyma—Rupia.*

SYPHILITIC psoriasis occasionally breaks out with the character of a protracted eruptive fever. Mr. Rose gives the case of Thomas Wills, aged 40, who was admitted into the Coldstream Hospital on the 30th of November, 1815, with a superficial ulcer of some days' standing on the extremity of the prepuce. He was dismissed Jan. 13, 1816. May 25, he was readmitted. He said he had had an attack of fever in the beginning of February, whilst on furlough in Essex; and after it had continued for some days, an eruption came out on every part of his body. The surgeon who attended him thought at first it was small-pox. It was probably, Mr. Rose conjectured, lichen, with papule of a large size. They have left large stains, which are slightly depressed, and becoming of a natural colour in their centres. The eruption had continued very thick for a week, and then went off in scurf.

This case is evidently of the same kind with the diseases described by Dr. Bateman, in the fifth volume of the Medico-Chirurgical Transactions, under the title of a "tubercular eruption of a syphilitic appearance, but curable without mercury." Dr. Bateman observes, that during the preceding two years he had seen from eight to ten instances of it, two only of which occurred in men. He speaks of the preliminary period lasting from a fortnight to three weeks, during which rheumatic pains, languor, and loss of strength, were present; and of roughness and soreness of the throat, with slight tickling cough on the appearance of the eruption, which he describes in these words:—"The eruption,

which had extended over the whole body in all the cases, at the time when I first visited the patients, consisted of a number of small circular spots, from one to two lines in diameter, slightly elevated above the surface of the cuticle, but flattened on their own superficies. They were at first of a dusky rose colour, smooth, and shining; but subsequently they became somewhat darker, or of a more purple or chocolate hue; and the surface of some of them at length exhibited a slight tendency to desquamation in the centre. This tendency to scale was generally most remarkable in the tubercles affecting the legs, which were somewhat larger than those of the rest of the body. A minute scaly crust was also occasionally formed upon the centre of some of those which were seated in the forehead, when the eruption was at its acme, or on its decline." He notices, besides, as present, inflammation of the tarsi and tunica conjunctivæ, and tenderness of the scalp.

The features of the following case, which was certainly syphilitic, and of the nature of psoriasis, identify it with the preceding:—

Charles Clarke, aged 38, towards the end of September, 1838, contracted a gonorrhœa that was followed in a week by an ulcer at the side of the frænum. A week after the appearance of the ulcer, having been exposed to cold and wet, he was taken with shivering, and pain in the back, followed by a hot stage, attended with pains of the back, legs, shoulders, arms, and head. This attack of fever had subsided in something more than a week, leaving him debilitated, when there broke out a profuse crop of slightly raised irregularly shaped flat spots, first on the thighs and legs; then on the body, and penis, and serotum; then on the arms, head, forehead, and face. The eruption was general in three days; on the fourth day, Oct. 27, he came to the hospital, and was ordered as an out-patient six grains of blue pill, with half a grain of opium, daily, and six grains of iodide of potassium in two ounces of decoction of sarsaparilla, three times a day. This plan he followed for three days, and was then admitted an in-patient under Mr. Tuson. He was covered with eruption, which at first sight looked like small-pox. The spots, which were elevated, and of a brownish-red colour, had a glistening appearance, from a

fine layer of semi-opaque lymph and epidermis on the summit of each. The mouth was sore from the mercury, which was ordered to be discontinued, and in its place four grains of the iodide of potassium, to be taken three times a day. The mouth continued sore for several weeks. After a few days the eruption began to decline, the patches lost their elevation; on their desquamating, brown stains were left, which gradually faded. He had no sore throat.

It is presumable that in this febrile form of the complaint no specific treatment is requisite.

II. SYPHILITIC LICHEN.—The eruption consists in acuminate pimples, of a red colour and variable magnitude, from the minutest size to a sixth or a fifth of an inch in diameter. They are either separate or in clusters. The two forms often coexist, the general eruption being of larger papulæ, interspersed here and there with oval groups of lesser ones. Sometimes the whole cutaneous surface is covered with extremely minute papulæ, the face and forehead having a swollen appearance. The separate lichenous papulæ are formed upon the orifices through which the pilar hairs come out. The point of each papula is grey, from lymph effused beneath the cuticle. After some days the spots become paler, a scurf separates, and a slight stain, effaceable on pressure, alone is left. As the first crop of pimples fades fresh ones often arise. Occasionally pus is formed in some of the papulæ, but there is no ulceration. The pus dries, forming a scab, which, when it separates, discloses no eschar or depression. Sometimes an eruption occurs, which it is impossible to dissociate from syphilitic lichen, in which all the red points fill with transparent fluid, and then with pus; or the eruption becomes pustular at once.

The distinguishing feature of the lichenous variety of secondary syphilis is, that the attack bears an inflammatory character, and is ushered in by symptomatic fever, which continues a longer or shorter time after the eruption has appeared. Syphilitic pains accompany the fever and eruption; they are commonly more severe than in psoriasis, and affect the joints in a greater degree, the knees especially, and the ankles, which are liable to become swollen. These pains are sometimes most severe at night. The throat is liable to be si-

multaneously affected in the same way as in psoriasis, namely, with inflammatory excoriation. Loss of hair occasionally attends this form of the disorder. Iritis is more frequently combined with lichen than with either of the other forms of cutaneous syphilis: this evidently has to do with the inflammatory state of habit that prevails in, and probably occasions, the lichenous variety. The bones are least frequently affected in this form of the disease. Mr. Carmichael, through whose original observations the characteristic features of the lichenous variety of syphilis were first determined, observes of his experience in it—"In a few cases swellings occurred over the tibia, and might be denominated nodes. They differed, however, from the syphilitic node in possessing much more of the inflammatory character, and in affecting the coverings of the bone and not the bone itself; for they appeared suddenly, and after continuing a few days as rapidly disappeared, without the exhibition of mercury." In other words, in Mr. Carmichael's experience, the periosteal affections in this variety of lues have the same character which the other local disorders present.

In the lichenous form of syphilis, as well as in the preceding, cases occur that are so trivial, although perfectly identifiable, as not to disturb the health sufficiently to render medicine necessary. The treatment of venereal lichen has to be conducted in reference partly to the febrile disturbance which attends it, partly to the vitiated habit of body from which it springs. In the febrile or inflammatory stage, confinement to bed, low diet, salines with antimonials, aperient medicine, and even venesection if the inflammatory symptoms run high, are to be prescribed. When the febrile symptoms are on the decline, if the patient appears to be quickly picking up strength and health, no further treatment may be then advisable. But if, as it frequently happens, the patient remains out of condition, the throat excoriated, and fresh papulæ appearing; or, no strongly marked febrile symptoms having ushered in the disorder, the patient has been from the first in a cachectic state only, one of the antisiphilitic medicines is necessary; and among these the iodide of potassium is to be preferred: it has appeared to me even more promptly efficacious in this

stage of this form of syphilis, than in psoriasis. The other palliatives of the same class are preferable to mercury. Nevertheless, in some cases of a protracted nature, here, as in psoriasis, an alterative course of mercury is to be recommended; but perhaps it is more useful from its general influence upon the system than for its specific influence on the disorder. In the inflammatory, or most virulent form of lichen, mercury is certainly prejudicial.

I shall now exemplify some of the principal features of the lichenous form of syphilis by the detail of cases, selected to illustrate the origin and progress of the complaint, and the rules of treatment above laid down.

Thomas Campion, mentioned by Mr. Rose, was admitted into the Coldstream Hospital, June 3, 1815, with a large, not very deep sore, on the edge of the inner membrane of the prepuce. It had no disposition to granulate, and he had an open bubo in each groin. The sore, from his account, had been present a fortnight, the buboes a week. The former was healed on the 14th of June; and on the 24th of that month, after feeling chilly and feverish for two or three days, an eruption of inflamed papulæ appeared over his body, and about his forehead and neck. On the 28th the febrile symptoms had disappeared; but the eruption was very thick, and his left eye was inflamed. The inflammation did not appear to have extended to the internal tunics. July 5th, his eye was well; the eruption had begun to fade, coming off in scurf. He had taken small doses of Epsom salts and antimonial powder since the attack of the first symptoms. This was omitted, and decoction of bark and nitric acid prescribed. July 12, the symptoms had nearly left him; the buboes were both healed. July 21, he was dismissed. He returned four days afterwards with violent pains in his limbs, increased at night. His ankles were swelled, and some fresh papulæ had appeared about his face and neck. By the use of the warm bath and Dover's powder these symptoms were removed. He was dismissed cured on the 21st of August.

In the next case given by Mr. Rose, lichen occurred after "an indolent sore close to the edge of the frænum, which had been present two months. It was healed in thirteen days, with some hardness and thickening." The pri-

mary sore, in the case immediately succeeding, is described as "situated at the extremity of the prepuce, having thickened edges, and some induration." In another, followed by lichen, upon subduing a phymosis, "a deep foul sore was brought into view on the left side of the frænum, of the size of a silver penny, with hard and irregular edges." This was healed, with much hardness, in twenty days.

Thomas Robins, aged 28, came under the care of Mr. Rose, June 29, 1816, for pain in his shin bones and knees, increased when he was warm in bed. A very copious eruption of lichen in large papulæ over every part of his body, with inflammation of both irides. The pains in the limbs had been present about a month; the eruption had appeared about a week; the inflammation of the eyes only three days: he had had a similar eruption, though not nearly so copious, about three months before. He got well without mercury; but at some date subsequent to the 6th of October, he had over his shoulders and buttocks, and at one time on the soles of his feet, a few small vesicles, which came in clusters on a thickened and elevated patch of skin. They soon filled with a puriform fluid, and when they burst left a thin scab. The thickened integument was of a dark red colour, of an irregular form, and in general about an inch in its longest diameter. It remained for a long time, but produced no effect on the general health.

Thomas Kelbay was admitted into the Coldstream Hospital, on the 16th of March, 1816, with a small deep circular sore, with hard irregular edges, immediately behind the corona glandis, and two small sores on the outer edge of the prepuce: he had likewise a purulent discharge from the urethra. May 8, the sore behind the corona was beginning to granulate. It had proved very troublesome, several deep sloughs having formed in it at different periods. A pustular eruption had appeared on his body and limbs. The pustules were very small, not much larger than pins' heads, and were on slightly elevated and dark red bases. He had pain in the loins, but no distinct febrile symptoms; tonsils enlarged; ulceration at the back of the pharynx. May 15, the eruption had extended to his forehead, chin, ears, mouth, and neck. Numerous

tubercles could be perceived under the integument on the inner part of the right leg; they were quite moveable, and half the size of garden peas. The right ankle swelled at night, and he complained of pain in the upper part of the tendo Achillis. May 20, threatened iritis of the left eye. 26, many of the pustules had burst, and formed a thin crust, and fresh ones have continued to come out. June 1, the eruption covered every part of his body. The pustules had increased in size, but were still a good deal smaller than those of small-pox; in the face they were beginning to scab. On June 15, July 1, August 14, and October 2, he had fresh attacks of pustular eruption, the last "fainter and with less disturbance than any of the preceding ones."

Elizabeth Sinclair, aged 25, was admitted into the Middlesex Hospital, Nov. 2, 1839. About six weeks previously she had contracted gonorrhœa, followed, in a week, by sores on the inner surface of the labium. About three weeks after this, she felt pains in the legs, and was languid and out of health. In another week the pains became general, affecting her entire person, accompanied with chills, followed by heat of skin, thirst, and loss of appetite. At the same time, a crop of lichen broke out upon the back and shoulders, which became thicker daily, and spread over the chest and abdomen, and forehead. The pains continued very severe for ten days, since when they have been partial and occasional only. At her admission, the papulæ on the back were of two kinds, large single papulæ, and groups of smaller ones; on the forehead they were of small size; on the chest and abdomen few and large only. The tonsils were swollen and excoriated. There were two small ulcers, without induration, upon the inner surface of one labium. Her gums were swollen, and had the appearance of being affected with mercury. Not to lose the benefit of the mercurial course which it was supposed she had begun, she was ordered five grains of blue pill every night, and the mouth became sorer. The eruption slowly faded, and the ulcers on the labium improved. About the 17th, a new crop of papulæ appeared on the back of the neck and behind the ears, which itched greatly. Nov. 20th, the mercury was discontinued, and seven grains of the iodide of potassium, in

decoction of sarsaparilla, were ordered to be taken three times a day. On the visit three days afterwards, a very manifest and striking improvement had taken place in her health and appearance, and she is now perfectly well.

Patrick M'Guinness was admitted an hospital patient, under the care of Mr. Carmichael, Jan. 7, 1812, on account of a small superficial ulcer on the prepuce, without any surrounding induration, that had existed three weeks, and a large tumor in the right groin, containing matter. Nitrous acid ordered. January 25, the ulcer of the prepuce had healed, the bubo had ulcerated, and the enlarged gland was projected through an opening on the skin, forming an ulcerated tumor of considerable size. Feb. 6, a thick eruption of small papule of a red colour had appeared on his face, neck, and shoulders, attended with considerable fever, and severe pains in his shoulders, elbows, knees, and ankles. He also complained of soreness in his throat and difficulty of swallowing. On examination there was not any ulcer, but a general inflammation of the fauces, and a peculiar raw and excoriated appearance of the back of the pharynx. He was directed to discontinue the nitrous acid, and to take the antimonial solution. Feb. 22, the eruption continued: many of the spots, after forming minute pustules in their acuminated tops, had declined in exfoliation of the cuticle, while fresh papule at the same time appeared in other parts. He complained of the severity of the pains, particularly in his knees, which shot along the muscles of his legs, but he did not complain of any pain affecting the tibia: his pulse was 112, with considerable thirst and restlessness. Twelve ounces of blood were taken from his arm, and the antimonial solution continued. The blood taken was buffed and cupped, and he felt considerably relieved after this depletion.

March 1st, he was directed to take decoction of sarsaparilla in conjunction with the antimonial solution, the febrile symptoms having nearly subsided, and before the 8th the eruption had every where declined, and, in some places, disappeared. He still complained of the pains in his joints, which, however, were considerably alleviated. As a remedy for these, fifteen grains of the compound powder of ipecacuanha were ordered: the decoction to be continued,

and the tepid bath to be daily employed. Under this plan his pains were soon removed, and the eruption disappeared, leaving the skin discoloured with indistinct red marks. March 15, he was discharged well.

On the 1st of May he returned, complaining of severe pains in his joints, and an eruption of papule on his arms. His pulse was 110, with thirst and general fever. He stated that since he left the hospital he was exposed to the inclemency of the weather, and that he had been affected with three several crops of the eruption, accompanied with pains resembling those of rheumatism. He was bled to sixteen ounces, and the antimonial solution ordered. The blood taken from his arm was thickly buffed. His pulse was next day reduced to 90, and the pains were considerably alleviated. 10th, the eruptions had declined, and there had not appeared any fresh spots. He stated that his hair was falling off. 17th, the ankles were swelled and painful. Alternative doses of calomel, with antimonial powder, ordered; half a grain of the former, and three of the latter, three times a day. Under this plan his pains were relieved, and his complaints to all appearance removed. Discharged on the 7th of June.

III. ULCERATIVE AFFECTIONS OF THE SKIN.—It has been already mentioned that ulceration occasionally takes place in protracted psoriasis of the common description; but the ulceration is superficial and limited, and it does not extend deeper nor materially wider than the mere surface of skin that has been the seat of the blotch; it is rather excoriation than ulceration, and it soon spontaneously cicatrizes. In that form of psoriasis in which the patches are clustered in groups, ulceration is more frequent, and it is liable to assume a virulent aspect, to destroy the whole thickness of the skin, and to evince a disposition to spread. I have never, however, seen the complaint in this form intractable to medicine, or presenting that degree of virulence which belongs to the ulcers that follow the eruptions now to be described. These are, lepra, tubercle, ecthyma, rupia. I have placed lepra first on the list, because its features are transitional between psoriasis and the other eruptions named. Lepra does not necessarily ulcerate; in this it approaches psoriasis,

as well as in its scaly character; but its ulcerative form, on the other hand, is liable to exhibit the utmost virulence, and on that account it deserves a place under the present head.

I am therefore surprised at reading, in Mr. Babington's notes to Mr. Palmer's edition of Hunter the following statement, which comprises what Mr. Babington has thought it necessary to add to the text, under the heads of *psoriasis* and *lepra*:—"Scaly eruptions are very common in venereal cases, but they differ little from those which occur from other causes. They appear generally in small circular spots, but they vary much in the degree of elevation, the size of the spot, and the depth of its colour; yet they never assume the coppery tinge of the tubercle. The colour is rather sandy, and is in almost all instances nearly effaceable by pressure. The difference of colour, the superficial origin of these eruptions, and the total absence of ulceration in all forms and stages, sufficiently distinguish them from tubercles." Now I have mentioned a case (page 352) in which *psoriasis* on the forehead left the true coppery stain to which Mr. Babington refers as peculiar to tubercle; and I have several times witnessed the super-vention of the ulcerative stages both of *psoriasis* and *lepra*, which I have described and shall exemplify. Mr. Carmichael gives an excellent plate of venereal *lepra*, with one of the patches in the crusted and ulcerated state.

**LEPRA.**—The following is Dr. Willan's account of siphilitic *lepra*:—"In the venereal disease circular patches sometimes appear, which resemble those of the *lepra nigricans* in size and colour, but which are not incrustated. The dryness and harshness of the skin, so remarkable in the *lepra vulgaris* and *alphoides*, do not occur in the venereal *lepra*, its patches, when somewhat advanced, being as soft and pliable as other parts of the skin. It is, however, proper to observe, that every patch originates from a small, hard, reddish, protuberance. As this gradually dilates, the increase of its circumference is not attended with an increasing elevation of the centre; on the contrary, the sides of the patch are somewhat raised, and the central part of it appears a flat surface, covered with thin white scales. The patches are generally distinct, and at a distance from each other. There is seldom seen any of them exceeding the

size of a shilling; yet it is probable they might obtain a greater magnitude if the progress of the disease were not arrested by the use of mercury. When the constitution is under the full influence of mercury, the sides of the patch shrink and become paler; the centre is also depressed, but the desquamation proceeds slowly, and the disease cannot be removed without a perseverance in the course for six or eight weeks. A circular red spot usually appears for some weeks in the place of every declining patch, and a minute shallow depression like a cicatrix is left at the centre; but no permanent discoloration of the skin remains. The leprous form of the siphilitic eruption takes place, like other venereal eruptions, at very different periods after infection in different cases. If no medicines were employed, it would at length terminate in ulcerated blotches."

Nothing can be more faithful than the preceding description; but it applies to the mildest form of siphilitic *lepra*, of which the deficiency of scales, mentioned by Dr. Willan, is a remarkable characteristic. But the picture of the disease is imperfect without the following touches by Mr. Carmichael:—"If mercury is not employed," observes Mr. Carmichael, "the eruption proceeds to ulceration in the following manner. Each spot is covered by scales, or by scurf, which is thrown off and succeeded by another; every succeeding scurf which is formed becomes thicker than the preceding, till at length it forms a crust, under which matter collects, and it becomes a true ulcer; in which state it spreads but very slowly." Reserving for future consideration the question of the propriety of using mercury in these cases, I would add, that in the most virulent forms of *lepra*, the quantity of desquamation is often considerable, the patch of inflamed skin being covered by numerous fine layers of white papery glistening cuticle; and that finally when a crust has formed of agglutinated secretion and layers of cuticle, the ulcer which follows on its separation is capable of spreading as rapidly as in any form of secondary siphilitic disease, assuming features which will be given with *ecthyma*.

**TUBERCLE.**—All the siphilitic eruptions which belong to the head of tubercle, are not ulcerative. A woman was a patient in the Middlesex Hospital, with a crop of red, glossy,

berry-like tubercles, of the size of peas, upon the lower part of the face, which, from her history, were probably siphilitic, and went away with mercury. A man who had been my patient with scaly eruption, several of the patches of which had gone into superficial ulceration, returned at the end of two months with oval tubercles on his back and shoulders, at the point where the scaly eruption had been. They were convex, of a light pink colour, rather mottled in appearance, some of them an inch in length. In some there was sensation, but not amounting to pain. He was otherwise in good health. Mercury was given without any effect. In three or four months afterwards these tubercles spontaneously went away.

Ulcerative siphilitic tubercles are of two descriptions: with the first I am practically familiar; of the second, I shall give Mr. Babington's description.

Common siphilitic tubercle is a raised, oblong, or circular convex patch of soft, thickened, red, inflamed skin, the surface of which, before long being excoeriated, becomes covered with a thin crust; that separating, discloses a foul or yellow ulcer, of greater or less depth. Tubercles of this kind are liable to form on the forehead, eyebrows, nose, and face; on the chest and back, and on the limbs. They are the source of the disfiguring ulceration to which the face is liable in siphilis. Upon the brow, the ulcer sometimes spreads in an irregular serpentine course, healing at one end while it progresses at the other. The ala or tip of the nose, however, are parts more frequently eaten away. The ulcer proceeding from this source is slow in its progress, and continues surrounded by a considerable extent of inflammatory thickening and redness. Upon the nose and cheek, ulcers of the present kind are liable to crust over; when it is only known whether the ulceration is progressing or not under the crust, by the continuance or cessation of soreness, pain, or burning in the part, and by the increase or diminution in the inflammation of the surrounding integument. These ulcers upon the body and limbs are more or less circular, seemingly deep from their raised, thick, red edge, and have a foul surface; and they enlarge very slowly.

The following is Mr. Babington's description of another form of tubercle:—

"The original seat of the tubercle is probably in the sebaceous glands, certainly in some structure which is below the surface of the cutis. This is sufficiently evident from its aspect at the period of its commencement. It appears, in the first instance, as a small hard substance, like a pea, which may be felt by the finger, before there is sufficient discoloration to attract the eye. At this period, the eruption is scarcely discernible if the light falls directly on the part, though, if it is viewed by a side light, the prominence is sufficient to cast a distinct shadow. However, this stage is of short duration; the inflammation soon reaches the surface, and the spot then wears the appearance of a small red elevation, evenly rounded on the surface. In the next place, the cuticle dies and becomes detached from the cutis; but it usually remains for a time, forming a horny cup, which covers the surface, and protects the formation of a new cuticle beneath. In this stage, it frequently resembles a large vesicle, but the appearance is deceptive. If the dead cuticle be removed by a probe, not a particle of fluid will be found under it.

"The tubercle may remain in this state with little change, except that it slightly enlarges, and that successive layers of cuticle desquamate from the surface. But it often happens that it goes on to ulceration. In such cases, the ulcer always commences at a central point, which is slightly depressed, and may be distinctly seen on the first removal of the cuticle, and which appears to be the orifice of the sebaceous duct. As the ulcer proceeds, it usually destroys the centre of the tubercle only, and leaves an indurated and elevated portion, by which it is encircled and separated from the sound skin. In the progress of the ulcer, this tubercular thickening continues to precede it, so that there is always a margin of red induration, more or less marked, as the powers of the system are greater or less; frequently of considerable breadth in those who are strong and vigorous, but in the feeble often so slight as to be scarcely distinguishable; yet in all cases leaving, as it subsides, the peculiar brown stain which is the chief characteristic of the tubercle."

ECTHYMA consists in an eruption of large flat pustules, with an inflamed base. They are of variable magnitude, from a third to more than half an inch

in diameter. They are seldom numerous; they are liable to appear on the body, on the limbs, and on the face. If the secretion at first forms a crust upon them, the crust does not remain, but the pustules shortly become ulcers.

The character of these ulcers is strictly phagedænic; not in the sense, indeed, in which that word has been before introduced in this account of syphilis, but in its general sense. The primary phagedænic ulcer has commonly an irregular outline, may eat deeply, and the discharge from it is capable of producing a specific ulcer by inoculation. The secondary phagedænic ulcers which follow ecthyma, or virulent lepra, or rupia, are, on the other hand, at their commencement, always circular; they are shallow, and inoculation with the matter secreted by them does not produce an ulcer. As the secondary phagedænic ulcer spreads, it commonly retains for a time its circular outline; the skin immediately surrounding it is red and inflamed, and slightly thickened, to the distance of a sixth of inch or more; the edge of the ulcer is yellow, with a few red points shewing through it; the ulcer does not go deeper than the skin; its surface is therefore level. The central part is often covered with healthy granulations, while the edge is eating on with the character above described. Approaching towards the edge, the surface becomes covered with a gradually thickening layer of adherent yellow secretion, with granulations shewing through it. Sometimes the surface of the whole ulcer continues a yellowish grey, with red points. The central part, after exhibiting healthy granulations for some time, will cicatrize; but this more commonly happens to one edge and part of the centre at once, the ulcer progressing with its unabated phagedænic character at the remaining segmentary margin. Sometimes the ulcer becomes elongated, and, healing at its middle, becomes two. Phagedænic secondary ulcers are extremely painful, and leave, on healing, disfiguring cicatrices.

**RUPIA.**—The eruption commences with a diffused redness upon a patch of skin. Upon this a flat vesicle forms, of the size of a silver penny or larger, the secretion in which speedily crusts. The same action continuing, new layers are successively formed, each larger than the last; so that what seems a yellowish-

black conical horn gradually arises from the skin. Below this the skin has progressively ulcerated, to an extent measured by the last formed layer of crust; a ring of inflamed skin surrounds the margin of the crust: if the crust is forcibly detached, the ulcerated surface is found red, vascular, and honey-combed—an organized secreting surface. The crust separating, the ulcer is liable to spread to a considerable magnitude, with the phagedænic character just described.

With either virulent lepra, tubercle, ecthyma, or rupia, indifferently, secondary ulceration of the integuments of the head and of the lower part of the face, has one character. It is always crusted; and if the crust is detached, a new one forms. The ulcer is circular, and most virulent at its edge; the centre sometimes healing, while the circumference or a segment of it is progressive.

Rupia is liable to appear over the whole body, but generally the spots are but few at a time. When the disposition is rife, large prominent vesicles full of serum sometimes appear among the crusted eruptions, and bursting, expose an excoriated surface, which dries up and heals.

[To be continued.]

---

## ON THE TREATMENT OF BRONCHOCELE.

BY JOHN CHARLES HALL,

F.L.S., F.M.B.S., Member of the Royal College of Surgeons, London, &c. &c.

(For the *London Medical Gazette*.)

---

THE first questions a student asks when the name of any disease arrests his attention, are (or ought to be), what is this complaint; where situate; on what does it depend? Possessed of this information, it behoves him, in the second place, to inquire, what are the most successful means of treating it.

The term bronchocele is derived from the Greek words, *βρονχος*, the *wind-pipe*, and *κηλη*, a *tumor*; it is named by the Swiss *gotre*, or *goître*; you frequently see it among the inhabitants of the hills of Derbyshire, where it is commonly known as *Derbyshire-neck*.

Bronchocele may be either simple or

compound: the *thyrophraxia* of Alibert is the most common form of the disease, and is nothing more than an enlargement of the thyroid gland, the skin covering the part being unaltered in structure, and not involved in the disease. For the most part it is free from danger, unless it becomes so large as to impede respiration. It is free from danger, simply because the duties of this gland in the economy of our nature are not so important as to be essential to the continuance of life. One case, however, is mentioned, in which the disease assumed a cancerous form, and the woman afflicted with it perished in consequence.

The seat of bronchocele, therefore, is generally found to be the thyroid gland, although cysts are sometimes formed in the cellular membrane surrounding it: this leads us to speak—

2dly, Of compound bronchocele.—Here we have the disease in the greatest possible severity: sometimes calcareous and other heterogeneous substances are connected with it; at others the gland itself is attacked with true sarcoma.

The term bronchocele, in England, always signifies simply an enlargement of the thyroid gland, which not unfrequently occupies a space extending from one angle of the jaw to the other; and also forms a swelling on the front part of the neck.

This swelling is more or less irregular in form. At the first it is generally of a soft spongy feel; the skin retained its usual hue. If the disease, however, remains for a considerable time unattended to, the veins of the neck frequently become varicose.

Prosser remarks—"The tumor generally begins between the eighth and twelfth years; it enlarges slowly during a few years, but at last it augments very rapidly, and forms a bulky pendulous tumor. Women are far more subject to the disease than men; and the tumor rapidly increases during their confinement in childbed." Sometimes bronchocele affects the whole of the thyroid gland, that is to say, the two lateral lobes and the middle portion; and here it sometimes happens that you may observe three tumors of unequal size. Sometimes after death the gland has been found perfectly free from disease, the tumor having formed among

the surrounding lymphatic glands and cellular substance.

Burns, in his *Anatomy of the Head and Neck*, remarks "that when one lobe of the thyroid gland is affected, it may extend in front of the carotid artery, and be lifted up by each diastole of this vessel, so as to have the pulsatory vibrations of an aneurism." Some authors have observed, also, that the right lobe is more frequently enlarged than the left; this fact, I believe, was first mentioned by Alibert; and Mr. Rickwood tells us "that he has witnessed the same thing in every case that came under his notice in the neighbourhood of Horsham, Sussex\*."

This disease is common in most of the valleys of the Pyrenees, Appennines, and Alps. In fact, there are certain localities where it is so frequent, that you can scarcely find a single individual altogether free from it. In the Tyrol and Corinthia there are to be found whole villages in which, without exception, all the inhabitants have these swellings; and they are considered indicative of additional personal charms. In many the swellings are so large as not to be concealed by any kind of clothing.

A state of idiotism is another affliction not unfrequently attendant upon bronchocele, particularly in countries where it abounds; yet all who are attacked with bronchocele are not idiots, or cretins as they have been called. In Italy and elsewhere it is met with in persons whose mental endowments are of the highest possible order. A patient whose case I shall shortly mention was a young lady of considerable talent, shewing an aptitude to acquire whatever she attempted to learn. Several writers, and among them Fodéré, have ascribed the state of the mind to the affection of the thyroid gland. This opinion, however, seems to have been arrived at without any reason; for in idiots the mental faculties are weak from their earliest years. In many, also, idiotism is complete where we find no enlargement of this gland, or even a tendency to enlargement, and in cases where the tumor is too small to impede the current of blood to the head. It would consequently appear that the cases in which weakness of intellect and

\* Vide Med. and Phys. Journal, 1823.

goitre have been observed coexisting, must have been accidental; and this conclusion appears strengthened, when I remember that I have of late frequently observed bronchocele in particular districts, and at the same time seldom or never observed any of the inhabitants to be idiots.

Mr. Cooper, in his last edition of his *Surgical Dictionary*, remarks, "that bronchocele is not confined to Europe; it is met with in almost every part of the globe. Professor Barton, in his travels amongst the Indians settled at Oneida, in the state of New York, saw the complaint in an old woman, the wife of the chief of their tribe. From this woman he learned that bronchoceles were by no means uncommon amongst Oneida Indians, the complaint existing in several of their villages. He found also that the varieties of the disease were the same as in Europe."

The great danger of bronchocele in this country, appears to be, as above stated, the difficulty of respiration produced by the pressure upon the wind-pipe by the tumor, and other glands which become enlarged; for by disordering the pulmonary circulation the pulse becomes quickened, irregular, and very frequently intermittent. A strong throbbing is excited in the region of the chest, followed, as some writers remark they have observed, by even fatal disease of the lungs; consequences frequently not supposed to have any connection with this disease, though, in truth, the bronchocele has been the primary cause of them.

#### *Causes of Bronchocele.*

It would appear from what we have stated—from the observations of all writers upon this subject—that certain districts tend to produce this affection of the thyroid gland. Some have gone so far as to assert that change of air is more efficacious than any remedy that can be used. Again, it has been attributed (and apparently with some degree of reason) to certain chemical properties in the water; and Dr. Odier gives credit to this theory, because he observed "that distilled water not only prevented the increase of the swelling, but also tended to lessen its bulk. However, every explanation is very unsatisfactory, particularly when we call to mind this passage in the writings of that justly celebrated physiologist, Humboldt. "Persons af-

flicted with bronchocele (he observes) are met with from Honda to the conflux of the Cauca, in the upper part of the course of the Magdalen River; and on the high flat country of Bigota, 6000 feet above the bed of the river. Now the first of these three regions is a thick forest, while the second and third have a soil destitute of vegetation; the first and third are particularly damp; the second is peculiarly dry. In the second and third region the winds are very tempestuous; in the first the air is stagnant.

#### *Temperature.*

	Centigrade degrees
First and second region ..	22 and 33
In the third .....	4 and 17

Again, the waters drunk by the inhabitants of Mariquita, Honda, and Santa Fé de Bogota, where bronchoceles occur, are not those of snow, and issue from rocks of granite, freestone, and lime. The temperature of the waters of Santa Fé and Mompox, drunk by such as have this disease, varies from nine to ten degrees. Bronchoceles are more horrid at Mariquita, where the springs which flow over granite are, according to my experiments, chemically more pure."

So much, then, for the influence of local causes in producing this disease, at the same time we must admit that certain districts are more subject to goitre, although there are few parts of England altogether free from it. This leads me to speak, lastly, of the

#### *Treatment of Bronchocele.*

I have divided bronchocele into two kinds — 1st, simple; and 2dly, compound; to the treatment of the former, however, I shall confine my remarks in the present paper. Without entering into a critical examination of the favourite plans of different surgeons, I shall extract a few cases from my note-book illustrative of the method of treatment that I found to be most successful.

CASE I.—Miss Mary R. æt. 17, somewhat below the middle height, thin, and of rather a sallow complexion, came with an enlargement of the thyroid glands, which she said she had been suffering under for the last six months, during three of which she had been under the care of a surgeon who had given her Tr. Iodinæ in large doses. The catamenial discharge, though not altogether

wanting, was pale and scanty, the periods being very irregular; the tongue was furred, with red edges; the bowels costive; frequent headache; and a disinclination to move about; fancied she is thinner since she took the iodine.

I thought it would be useless to attend to the enlarged gland until her general health was improved; I therefore ordered her to live upon

New milk with meat once a day; the meat to be dressed in the plainest manner; to avoid pastry and vegetables, and to take as much exercise as her strength would permit.

I likewise ordered her to take the following pills three times a week, at bed-time.

R. Pil Hydrarg. gr. ij.; Pil. Rhei co. (E. P.) gr. viij. Misce ft. pil. ij.

She also took the following mixture:

R. Inf. Gent. co. ʒij.; Sodæ sesquicarb. bonatis, ʒj.; Tr. Aurantii, ʒss; Aq. Cinnam. ʒiiss. Capiat coch. iij. mag. ter quotidie.

Under this plan of treatment she gradually recovered her health; the yellow appearance of the conjunctiva was exchanged for the hue of health; the sallowness of the skin was removed; the bowels were in a more healthy condition, to use her own words, "if it were not for my neck I should be quite well, but it hurts me when I sing."

The bronchocele during this time (about one month) remained much the same: if any thing, it rather diminished than grew larger; it was, however, still very large, the whole gland being affected. The tincture of iodine having failed, as well as the local application of it, I determined to adopt a plan that I had before found to be successful, and which I have every reason to think will succeed in the great majority of cases. I first ordered the application of six leeches to the part; these were repeated three times during the first ten days, the part being well fomented three times a day with warm water.

R. Liq. Potassæ. ʒj.; Tr. Card. Co. ʒji. Misce Semat. ℥ xv. ter quotidie. ext. int. Zingiberis.

The liq. potassæ was gradually increased to ℥xxiv. three times a day. I then thought it advisable that some local application should be made use of, and the following ointment was ordered to be applied (rubbed in with the hand) twice a day, the part being first

well washed with warm water for at least a quarter of an hour.

R. Potass. Iodidi, ʒj.; Ung. Cetacei, ʒj. Misce ft. ung.

This plan of treatment was steadily followed during the months of June, July, and August, the patient taking once a week a pill composed of pil. hydrarg. et ext. colocynth, with a rhubarb draught the following morning. The last week in August she came to me without the slightest remains of the bronchocele—perfectly recovered.

CASE II.—Mary Padley, æt. 14. Her mother has a large bronchocele, which has not increased for some years past. "Her daughter had some difficulty in swallowing, and at length they found a small tumor." It is now about the size of an orange, situated on the right side of the gland, and gradually increasing towards the other side of the neck. She is very much out of health; complains frequently of pain in the head; a great disinclination to take food. Has menstruated once, about two years ago, but never since. The mother, who lived formerly at Derbyshire, says that all her own family are subject to goitre. The girl is of rather light complexion, blue eyes, thin and tall.

To live upon a milk diet, with meat once a day; to avoid fruit pies, (upon which she says she has almost lived for the last two years,) and vegetables.

R. Pil. Hydrarg. gr. j.; Pil. Aloes, c. Myrrh. gr. iv.; Ft. Pil. alternis nobis, sumenda.

R. Vin. Ferri. ʒj.; Aq. ʒss. M. ft. haust. ter quotidie sumenda.

For some time subsequently I treated this case with the tincture of iodine, but the tumor increased gradually till I substituted the liq. potassæ in the same doses as in the former case. The gland was leeches twice, and rubbed with the same ointment. In three months the swelling had altogether vanished, after which the girl was directed to attend particularly to her health, to keep her bowels open, and to avoid improper food. I heard from her a few days ago; the bronchocele has not returned.

CASE III.—John J., a boy æt. 13. Left lobe affected; but small, not larger than a walnut. A blister was applied; after it had healed, leeches, alterative medicines, and liq. potassæ. This case was cured in six weeks. No local

application after the blister and leeches, except friction with the hand.

CASE IV.—Mrs. R. (the aunt of Case I.) observed about three years ago that shortly after her last accouchement a swelling appeared in the front of her wind-pipe; it has gradually increased in size, and is now very large, extending down the neck. She complains of “her health being very bad.” Her hair is of a light colour, rather inclining to a sandy tinge; the eye-lashes are light; the eyes blue; the complexion pale; the whole appearance enemic. She was ordered blue pill and colocynt, with some bitter infusion and soda; after which leeches were applied to the tumor; a blister afterwards. The gland to be well fomented with warm water, after which the following ointment to be applied twice a day.

R. Potass Iodidi, gr. xxx.; Pulv. Iodinæ, gr. x.; Ung. Cetacei ℥j. Misce ft. ung.

She is now taking mxxiv. of liq. potassæ three times a day, and when last I heard from her the bronchocele was gradually diminishing. At some future period I will inform your readers of the result of her case.

I could multiply these cases, were it necessary; but must not longer intrude. I will only remark that I think we may conclude from what has been stated, 1st, that although it abounds in certain localities, that we know not on what it depends; or why it should abound more particularly in Switzerland or Derbyshire than other places; 2ndly, that we have no reason for concluding that goitre should produce *cretinism*, although the two are frequently combined; [Dr. Wilson remarks that “he has observed epilepsy and bronchocele to exist in the same person;”] 3dly, that it is highly important to attend to the general state of the secretions before attempting to make use of specific remedies; and also that considerable advantage appears (in the cases I have seen) to result from fomenting the part affected with warm water (previous to using the iodine ointment); the application of blisters, and the local abstraction of blood by leeches; the exhibition of liquor potassæ, and alterative medicines. At some future period I shall be happy to resume this subject; for the present I refrain from trespassing longer.

Bath Place, Kensington,  
Nov. 1839.

ON THE OBTAINANCE  
OF  
CERTAIN PHYSICAL LAWS IN  
THE ANIMAL ECONOMY.

To the Editor of the Medical Gazette.

SIR,

I HAVE inclosed for publication the following paper, upon a subject which, as far as I am aware, has been hitherto unnoticed. Should you deem it of sufficient importance, its insertion in your valuable journal will oblige,

Your obedient servant,  
CHARLES FERNELEY,  
M.R.C.S.

Denton, near Grantham,  
Oct. 30, 1839.

Man, though endowed with mental faculties in addition to possessing an organized frame most perfectly adapted to his varied relations with the surrounding world, has nevertheless that structure governed by some of the laws which regulate not merely the frame of inferior animals, but also the relations and conduct of inorganic matter; and upon the conformity of his structure to these laws (they being subject to the influence of vitality) does his health, nay, in many cases his very existence, depend. To illustrate some of these is the object of the following remarks.

One of more importance than on first view we should be inclined to imagine, is the general rule, that when an arterial trunk divides, the sum of the diameters of its branches is greater than the diameter of the trunk; and, as the necessary consequence, the combined circumferences present a greater superficial extent than the circumference of the trunk. The same is observed of veins. The analogous case in inanimate nature is the conduct of running water, of which two equal streams do not, when united, occupy a bed of double surface: the law being, that when several tributary streams unite, the superficial area of the fluid mass is less than that previously occupied by the separate streams\*. No river affords a more striking illustration than the Mississippi, which is half a mile wide at its junction with the Missouri, the latter being also of an equal width; yet the united waters have only, from their

\* Lyell's Geology, vol. i. p. 266.

confluence to the mouth of the Ohio, a medial width of about three-quarters of a mile. The junction of the Ohio seems also to produce no increase, but rather a decrease of surface. The St. Francis, White, Arkansas, and Red rivers, are also absorbed by the main stream with scarcely any apparent increase; and on arriving at the sea at New Orleans, it is somewhat less than half a mile wide\*.

The parallelism of the two cases is such, that we may conclude that the same cause which governs the one has evident connexion with the other. We will illustrate this disposition in the case of arteries, as being of greater interest to the physiologist. In order to understand the *rationale* of this law and its dependencies, it is necessary before proceeding further, to state, that in these remarks the term velocity is intended to express the space over which any particle flows, divided by the time, without any reference to the volume of the current. By the terms rapidity or velocity of the current or discharge, is meant the quantity which the vessel under consideration is capable of discharging in a given time, and which quantity will be equal to a volume of fluid, having the area of the orifice for the base, and the velocity for its height†. We must also assume as postulates, that the transverse sections and orifices of the arterial tube are circular, and that in a healthy state their elasticity is such as to preserve their parietes in immediate contact with the contained blood; they being capable of dilatation upon an increase, and of contraction upon a diminution of that fluid.

But to proceed: we will suppose any transverse section of the blood, *i. e.* a volume possessed of infinitely small length, but having a certain determinate area to be moved forward by the circ-

ulating forces; this, in its turn, arrives where the artery divides. Then must the sum of the areas of the branches be not unequal to the area of the trunk, lest the equilibrium of quantity be destroyed; were they less, there would be partial stagnation; were they greater, vacuity, both of which may be considered incompatible with the provision of arterial elasticity. Now circles are to one another as the squares of their diameters (Euclid, xii. 2), and therefore will the conjoined diameters, and consequently the circumferences or superficies of the branches exceed those of the trunk from whence they spring. If not, let them be equal to it. Suppose an artery having a diameter of 4 to bifurcate, and the diameters of the branches to equal 2 each; then will  $4^2$  or  $16 = 2^2 + 2^2$  or 8, the greater to the less. Therefore it is impossible (the forces and times being uniform) for those branches to carry away the fluid from a corresponding trunk, whose diameter much exceeds  $2.8282$ ; a proportion apparently coinciding with the example given of the Mississippi.

In order to prove whether these relative dimensions are observed in the arteries, I injected several from a sheep, and found that the squares of the diameters of the trunks, and those of the branches, so nearly coincided, that the trifling difference which existed might be considered owing to inaccuracy of measurement, which would only amount to the square root of the difference, and which can scarcely be wondered at, since each unit was only the one-fortieth part of an inch. The vessels were dissected out, their cut extremities tied, and wax injected whilst they were immersed in tepid water. The following are some of the results:—

Diameter of Trunk.	Diameter of Branches.	Or squared.	Difference.
9.	7.5 + 5.	81. = 81.25	0.25
7.2	6. + 4.	51.64 = 52.	0.36
3.5	3. + 2.	12.25 = 13.	0.75
7.	5. + 5.	49. = 50.	1.
17.	10. + 10. + 9.5	289. = 290.25	1.25
10.	7. + 7. + 2.	100. = 102.	2.
4.5	3.5 + 3.	20.25 = 21.25	1.
8.	4. + 7.	64. = 65.	1.

\* Op. cit. p. 282.

† Playfair's Outlines of Natural Philosophy, vol. i. p. 195.

The three first examples were from the mesenteric artery of a sheep, the next three from the aorta and iliac arteries, and the two latter from the horse.

This arrangement of the vessels has reference to several important effects. One is, that the velocity of the blood is uniform throughout the arteries, as depending chiefly upon each individual ventricular systole, of the quickness of which the pulse thus becomes a measure, as well as of its frequency; for when a current is in a state of equilibrium as regards its forces, the velocity in different transverse sections may be very unequal, on account of the variations of the areas of those sections, through all of which the same quantity must flow in the same time, "the mean velocities being inversely as the areas of the sections\*." This uniformity of velocity affects the rapidity of discharge, for the quantity of water that issues in one second through a given orifice is equal to a column of water, having the area of the orifice for its base, and the velocity with which the fluid issues for its altitude†. Consequently the rapidity of discharge through the arterial branches, as measured by the forces of the current, would be as their respective areas. This agrees with the experiments of M. Pousville, who found that the force of the current of blood in all arteries sufficiently large to be experimented on, is relatively the same; that in the aorta, for example, bears the same relation to its diameter, as that in the artery at the wrist does to its diameter; so that the diameter of an artery may be taken as a measure of the force of the current of blood in it." Thus we derive confirmation that a ratio of equality exists between the areas of an artery and of its branches.

There is an apparent discrepancy with respect to the velocity being constant; for it is said, that the stream of blood will, like a current gradually growing wider, become slower as it becomes more distant from the heart; but this discrepancy vanishes upon attending to the distinction between velocity and rapidity, or velocity of discharge, as given above.

Hitherto we have disregarded the effects of friction. Theoretically speaking,

there is a zone of comparatively quiescent particles (whose velocity is least in immediate contact with the sides of the tube, and gradually increasing with the distance from the circumference) surrounding the central stream, so that the water which issues is found by experiment to suffer a diminution in the ratio of 5 to 7, and thus, the effective current is equal only to that of an area,  $\frac{5}{7}$ ths of its actual dimensions; and in the passage of water through long tubes of equal areas, the discharges are in the inverse ratio of the square roots of the lengths. That these effects must exist in the arterial tubes cannot be doubted, although they may be much modified by their elasticity. But the friction is variable, depending upon the force of the heart's action, and the contractile power of the arteries, and it increases as the square of the velocity. Now the resistance being considered constant, which it is during each pulsation in any particular vessel, it follows that the quicker the circulation the greater the distension of the arterial trunk, and as a consequence, the still greater increase of size of its terminal branches: for, if we assume the law that these are in the squares of their diameters equal to the square of the diameter of the trunk, a trifling increase of this would in much greater degree enlarge those. May not the converse of this explain the therapeutic action of nauseants in subduing inflammation? They, by diminishing the force of the circulation, would diminish the friction, and thus mediate lessen the volume of the capillaries.

That those diseases which affect the natural magnitude of the arteries should affect the circulation through them, is evident from the foregoing remarks. In the early stages of aneurism, if there be a simple dilatation of the whole circumference, or of its greater portion, as occasionally happens, we should expect the velocity of the blood to be diminished; but as the trunk resumes its original calibre, the velocity would return to its general standard, according to the law previously mentioned. Dr. Black's 9th corollary, recorded in the MEDICAL GAZETTE, for July 14th, 1838, page 643, coincides with this. "The *vis a tergo* being a constant force, the velocity of the blood is inversely as the diameters of any set of vessels compared with the capacities of those which immediately precede them." When the

\* Playfair's Outlines, vol. i. p. 205.

† Opl. cit. p. 195.

passage from the artery is narrow, and the fundus of the aneurismal sac greater in proportion to its distance from the vessel, as is commonly the case, it would not very much impede the circulation through the trunk, for that in the sac would, from the influence of its form, the communicating not be in a very active state, and hence the tendency to coagulation. But in the more advanced stages, when the coagulum obstructs the current, the artery adapts itself to its diminished contents, so that its lower continuation is found preternaturally small and contracted\*. And when any considerable artery, or even the aorta, becomes either much obstructed or entirely obliterated, the collateral arteries which originate above the swelling are manifestly enlarged to carry on the necessary circulation through their anastomosing branches; this enlargement progressively corresponding with the diminution of the calibre of the vessel. This happens whether the obliteration occur by fibrinous coagula, osseous concretions, or morbid growths filling the cavity, or by the advanced progress of aneurism to a spontaneous cure, or by the application of ligature, the curative effects of which, whether Hunter's, Bradsor's, or Dr. Wardrop's method of operation be adopted, the law of equal sections fully explains. In varicose aneurism, we are told in Cooper's Dictionary, page 181, that the artery will become larger above, and smaller below the varix, and a solution given of its cause, by no means incompatible with, but such as would actually be the effect of this law, which, however, is not hinted at. That these effects depend upon the law of equal sections is evident, for the circulating force being constant, the volume of fluid will not escape unless the combined areas of the branches equal the area of the trunk: one branch, perhaps the principal, is obliterated or obstructed, the others enlarge, to supply the deficiency. And when, after a lapse of some months, the circulation becomes carried on exclusively through the insculating branches of an artery, or arteries, near to the course of the obliterated trunk, the other collateral vessels diminish to their previous dimensions. And if the branches enlarge, as happens to all in growing bodies, and to the arteries of particular parts, when the parts

themselves increase their bulk, and at the same time retain their vascular structure, the trunks of those arteries must also enlarge. It is well known that the uterine vessels grow much larger in the time of utero-gestation; the same has been observed in arteries supplying tumors, enlarged spleens, testes, &c.; so that I should suppose, says Dr. Wm. Hunter, "it will be found universally true in fact, and the reason of it in theory seems evident."

There is, perhaps, no pathological condition of the arterial system which better illustrates the obtainance of this law than that which occurs during an attack of inflammation. Whatever theories of the proximate cause be adopted, the redness, the primary swelling, and pain of tension, are universally allowed to depend upon an increased volume of the capillaries; but this increase should, if the law of equal sections be true, be also accompanied by an increase of area of the whole length of the supplying artery. Dr. Hastings says, that "the capillaries are first affected, and the small arteries of the web are occasionally enlarged." Professor Alison, in a paper on the vital properties of arteries leading to inflamed parts, as reported in MEDICAL GAZETTE, vol. xvi. p. 744, informs us that in all cases experimented on, the artery leading to the inflamed part was larger in its whole length than that of the sound limb. Dr. Marshall Hall tells us "this enlargement of the blood-vessels is not confined to the minute arteries, for the larger vessels in the immediate neighbourhood of the inflamed part also become enlarged\*." Professor Graves, in a communication on inflammation and the motor powers which cause and regulate the circulation, says, "the capillaries have the initiative; with them commences the enlargement which afterwards extends to the smaller arteries, and from them to the larger branches." Further proofs of the action of this law in inflamed parts may be taken from the means of cure. The local application of cold, by contracting the smaller, would diminish the larger trunk from whence they arise. In the MEDICAL GAZETTE, vol. xviii. p. 500, is an account of otitis checked by pressure on the common carotid, which exemplifies the converse. Diminishing the quantity of circulating

\* Cooper's Dictionary, p. 112.

\* MED. GAZ. new Series, vol. ii. p. 581.

fluid acts in a similar manner. The immediate relief obtained by bleeding from a large orifice may arise, not merely by arresting the return of blood to the heart, but partly also by having increased, during the continuance of the flow, the number of large branches (for veins are the continuations of arteries), and as a consequence, mediately diminishing the area of the vessels. But if there is an undue proportion of blood determined to any part, some other part must have less; hence, the small and weak pulse observed in most visceral inflammations; hence, the efficacy of counter-irritants, both internal and external, applied to remote organs, and the obvious propriety of the admonition never to stimulate an inflamed part. I have been thus prolix on some of the dependencies of this law, because I think it will give a philosophical explanation of many facts the rationale of which are involved in obscurity. I have neglected experiments, not only because opportunities on the human subject are "few and far between" to a country practitioner, but because there is often an almost involuntary contortion of facts to suit the theory, from which possibly I might not be free, especially as there is no undeviating standard of comparison. I have, therefore, drawn largely for confirmation from facts detailed by others, especially from the Dictionaries of Cooper and Copland, and from the *MEDICAL GAZETTE*, considering them as an epitome of the experiments and opinions of those eminent men, whose works are quoted in those leviathans of medical literature.

Oct. 1839.

## ENCYSTED DISEASE OF THE KIDNEYS.

*To the Editor of the Medical Gazette.*

SIR,

THE following case of extensive organic disease may perhaps be considered interesting, more especially as an opportunity was afforded of watching the gradually increasing symptoms, from those of mere disordered function, to those of diseased structure. Should you consider it worthy a place in a page of your

most valuable journal, its insertion would much oblige, sir,

Your obedient servant,

JOHN TAYLOR.

Westbourne Terrace, Bayswater,  
Nov. 20, 1839.

Mrs. Mills, æt. 56, the mother of three children, the youngest being fourteen years of age. She states that from the age of nineteen she has laboured under a violent and almost continued cough, attended with the expectoration of a viscid phlegm, most abundant upon rising in the morning; the cough was always aggravated after meals, frequently causing the rejection of the whole or part of her food. This continued for years, gradually becoming worse every winter, till at last it assumed the character of habitual winter cough, the quantity of expectoration being very much increased, and the frequency of the vomiting so much so, that she lost flesh rapidly.

She states that in the year 1812 she was attacked with inflammation of the liver, (from her description, of a violent character) for which she was salivated; recovering slowly, she has ever since laboured under a torpid state of that viscus, requiring mercurial pills and senna to be administered very frequently.

In February of 1836, my attention was more especially drawn to her case, on account of dropsy having made its appearance in the form of anasarca, ascending from the ankles to the abdomen, which at the same time afforded a distinct sensation of fluctuation; the face also was slightly cedematous, and there was some pain complained of in the right side under the ribs, increased upon pressure, together with a "dragging sensation, as of something growing to the side." The cough and expectoration, which during the previous six months had been less violent and abundant than formerly, now became very frequent and profuse; the quantity of clear viscid sputa expectorated was very large, and the attending dyspnoea urgent; the inferior portions of the thorax were dull on percussion, and the respiratory murmur absent; although, where resonance did still exist, there the murmur was puerile, and the râles mucons. The urine was apparently natural both in quantity and quality. (Albumen alone being tested for). The rhythm of the

heart was normal, its action being only increased in frequency. At this time she was visited by a skilful practitioner, who had formerly attended her, under whose judicious treatment she soon regained her accustomed health.

At this period her cough increased, and the quantity expectorated was still greater, with efforts which continually caused the stomach to discharge its contents, until it was so irritable as scarcely to be able to retain any portion of solid food; if at any time the quantity of phlegm diminished, she felt "oppressed," and the dragging sensation in the right side aggravated.

In July of 1838, I was requested to see her again, for what was supposed to be a state of salivation, since it followed the use of pills containing mercury. The tongue, mouth, and fauces, were covered with isolated sloughs of mucous membrane resembling aphthæ; the gums and cheek of the left side appeared one mass of putrefying matter; shreds of which occasionally came away in an increased flow of saliva. Externally the parts were much swollen, the adjacent glands enlarged and exquisitely painful. Her usual cough had been entirely absent for upwards of a month, but the stomach was more irritable than ever, ejecting a similar kind of sloughy matter to that in the mouth. The pulse was quick and weak, with great prostration of strength, and her complexion sallow, much resembling that of a person labouring under malignant disease. The treatment was first directed to the relief of the more urgent sickness; she therefore took the following, which after the second dose had the desired effect.

R. Acid Hydrocyan. Dil.  $\mathfrak{m}$  iv.; Sodæ Sesquicarb. gr. x.; Aq. Cinnamom.  $\mathfrak{z}$ iss. M. 4tis. horis sum.

so as to enable her to retain upon the stomach some slight nourishment, with two grains of disulphate of quina three times in the day, the bowels being for a time regulated by enemata.

To correct the fœtor, and tend to the separation of the sloughs, she used a lotion of sodæ chlor. (one part to sixteen of water,) alternating it, as the ulcers were exposed, with an astringent gargle of decoction of bark and tincture of myrrh. In a fortnight she was well, except an ulcer in the cheek, apparently kept open by the irritation from two of

the molares which were imbedded in it: their extraction soon allowed it to heal.

All she complained of during the subsequent twelve months were occasional cramps in the various parts of the abdomen and legs.

Last July, she had a return of aphthæ, only this time they affected the right side of the mouth and right cheek more particularly, which went through the same stages as formerly, and admitted of the same mode of cure, even to the necessity for extracting the molar teeth on that side; but during this attack the concomitant swelling of the face and neck was more generally diffused, and of an erysipelatous redness; the pain also was of a more severe character, and continued until the ulcers were entirely healed. The medicine which most relieved this last symptom was a gargle made by dissolving  $\mathfrak{z}$ ij. of extract of conium in  $\mathfrak{z}$ vi. of water. Although much emaciated and weakened, still she got pretty well again, until the middle of September last, when her bowels became more than usually constipated, her accustomed pills in double doses not having the same effect as formerly; the abdomen became very sore and tender on pressure; "the growing to the side," as she termed it, increased so much as to cause her to incline to that side for relief.

One morning, upon going to stool, a large quantity of dark-coloured blood passed, which was soon followed by repeated evacuations of nothing but blood, both in the fluid and coagulated state, and producing such a state of weakness as to leave little prospect of her recovery, should it continue much longer. Pulse was almost imperceptible; vomiting as urgent as upon former occasions, alternating with the melenæ. At this time also the same medical gentleman visited her; and we agreed, since the treatment could only be palliative, to give her some gentle bitter with a diffusible stimulant, and to keep the bowels open by a form of pill, the chief ingredients of which were pil. aloes c. myrrhâ, with a little of the hydrarg. c. cretâ. She gradually improved under this plan of treatment, with a few variations, and no return of melenæ took place for a month.

But upon the expiration of that period, a sudden discharge of no less than a pint of fluid blood occurred from the bowels, reducing her at once to the same

helpless state as formerly. This last attack was preceded by severe shivering, almost amounting to rigors, for several hours, and by distension and cramps in the abdomen and right side as before; but now they were much more urgent, and particularly acute in the left lumbar region. We could feel in the right hypochondrium what few would have doubted to be the liver, hard and tuberculated, being lost to the touch under the ribs above, and presenting a distinct line of termination below, a little above the umbilicus.

From this state of weakness she rallied only to pass into one of collapse; the pulse became irregular and intermitting, the breathing quick and laborious, the speech was soon entirely lost; and apparently unconscious of all around, she frequently placed her hand on the left lumbar region, as though in pain: pressure over the right hypochondrium now alone aroused her; occasionally she was violently convulsed, and drawn laterally almost double. Fæces began to pass involuntarily, but it was observed no urine was voided that could be perceived. She lingered in this state four days, and died on the 27th of October, after a violent tetanic spasm.

*Post-mortem appearances.*—Corpse much emaciated. Head was not examined. Chest: Lungs perfectly healthy in structure, lower lobes congested with dark blood mixed with a frothy serum. Heart of its natural size and capacity, valves healthy.

Abdomen: no portion of the liver could be seen while the parts remained *in situ*, its place being occupied by what appeared at first sight to be a large encysted tumor, unconnected with any of the abdominal viscera; but which, upon closer examination, we found to be the right kidney. It occupied the right lumbar region, extending as low as the third lumbar vertebra: passing forwards and upwards, obscuring entirely from view the junction of the ascending with the transverse colon, it reached the inferior margin of the cartilages of the false ribs, and passed for some little distance under them, above which point it was slightly overlapped by the lower margin of the right lobe of the liver; its circumference bore the same proportion to its length as the width and length of a healthy kidney bear to each other, so that it still resembled that viscus in shape.

There was a covering of peritoneum

before it, although very delicate from its extreme distension, which was not adherent to any surrounding parts. It might be compared to a bunch of grapes, of a very large size, in the form of a kidney; the cysts of which it was composed being externally very numerous, and so distended with fluid as, to the touch, to resemble marbles, each cyst upon an average being about the size of one, and none exceeding that of a walnut. Upon making a longitudinal section of it, as well as of the left, (which was exactly similar in structure, only less in size, but still visible upon first opening the abdomen,) these cysts were found to be packed so closely together as to start from their places without pressure; upon puncturing one, its contents would be forcibly ejected in a full stream. They resembled in miniature the cysts in one form of ovarian dropsy containing like them fluids of various consistencies and tints of colour; some perfectly transparent, others opaque, many gelatinous, and a few containing pus; but they did not communicate with each other, nor was one contained within another, as in encysted ovarian disease. The pelves of the kidneys were still discernible, although very much dilated, and were the only parts of the natural structure remaining.

Liver was rather smaller than natural, somewhat indurated, and very much tuberculated; a few of which tubercles were in a state of suppuration. In many parts were small cysts, similar to those in the kidneys, containing pure serum.

The stomach was so soft, and its coats so thin, as to give way in several places by the efforts used to break through the gastro-hepatic omentum; its inner surface was unusually pale, and void of rugæ. Spleen was very small indeed.

The small intestines were very much congested, so that you could distinctly trace some of the smallest ramifications of the blood-vessels, and their anastomoses.

The colon was sound to appearance externally, but in three points, viz. at the junction of the ascending with the transverse, the transverse with the descending, and at the sigmoid flexure, there were extensive ecchymoses under the mucous membrane, filling up the sacculi there situated, and so encroaching upon the canal of the gut as to render it almost impervious at those portions.

The uterus appeared healthy, but the

os and cervix, when a section of them was attempted, were found to be of a scirrhus hardness, cutting like cartilage. The ovaria were free from disease. The bladder was quite empty.

### CASE OF OVARIAN TUMOR.

*To the Editor of the Medical Gazette.*

SIR,

IN consequence of a severe illness, and absence from town, it is only lately that I have been able to look over the autumn numbers of the GAZETTE. I observe a case, narrated by Dr. Henry Davies, of ovarian tumor, bursting at the navel, and send you one similar, which occurred under my own eye, when one of the house-surgeons here.

Mary Macpherson, æt. 33, married, of Argyleshire, August 26th, 1834.—Two years ago, towards the conclusion of pregnancy, a swelling appeared at the umbilicus, and gradually enlarged. It now presents an umbilical hernia, about the size of a pullet's egg, containing a knuckle of intestine, which is easily reducible. Five weeks after appearance of tumor, matter formed, and made its way out at the umbilicus, where a small opening still exists, through which a probe can be passed directly backward for five inches, but not laterally. Discharge is copious, fetid, and sero-purulent. She says she had a stitch in her side before the matter appeared, but it cannot be ascertained whether she had peritonitis. She alleges that, before the opening formed, she passed pus in her urine. Complains much of pain in her back, but in other respects is tolerably well.

There was considerable difficulty in getting a clear account of her case, as she could not speak a single word of English. The pus spoken of had probably been sediment in her urine.

Various opinions were given on this case, some regarding it as abscess external to the peritoneum, and others thinking it a circumscribed one formed in the peritoneal sac by adhesions of the neighbouring viscera. This latter was my own opinion, in consequence of a dissection which I had seen of a patient who had an opening in the very same place; in whom the probe passed in a similar direction, and to a similar depth,

and who was supposed to have abscess of the liver. The case turned out to be circumscribed abscess, formed by chronic peritonitis. This Highland woman's story of "the stitch in her side" strengthened the supposition.

Dr. M. S. Buchanan introduced a dilator into the fistula, and expanded it so that the finger could be passed in, when a large quantity of fluid escaped. A large pasteboard compress, with a hole in its centre, was then applied by a bandage, with the view of keeping the sides of the abscess in contact, while the matter might flow out at the opening. It was found, however, that the pus did not get free vent, and a large catheter was introduced and retained, through which about six ounces were daily discharged. On Sept. 29th it was reported that the discharge had diminished to an ounce or two daily, and that a probe could with difficulty be introduced downwards, instead of backwards. This indicated that the cavity of the abscess was contracting. She was then put on calomel and opium till the mouth was affected, while the discharge entirely ceased for a fortnight.

On Oct. 24th above three ounces of greenish pus were discharged, very fetid; and on the 27th about four ounces more. There had been no poking at the abscess all this time to irritate it.

On the 29th, at 4 A.M. after a severe rigor, she was seized with acute peritonitis, which, notwithstanding the most active treatment, carried her off in 38 hours.

*Inspection*, Oct. 31st.—By making a semilunar incision on each side of the umbilicus, its connection with diseased parts was preserved. Adhesions to the omentum majus were found. A narrow sinus, about an inch long, led to the cyst from which the matter flowed. This being laid open, was found to form a part of the left ovary. Its walls were a quarter of an inch thick, it was nearly four inches long, and it was lined with a dark-coloured, vascular, flocculent membrane. On its inner surface were two tumors, soft, like warts, but covered with a membrane, each about the size of the point of the little finger. Their surfaces were covered with papillæ, from which arose, on one side, single hairs; on the other, tufts of hairs, like the eyelashes.

Peritoneal surface of ovaria, uterus, and neighbouring parts, in a high state

of inflammation, covered with false membrane. Orifice of the left Fallopian tube exceedingly vascular and dark red. Inflammation was traced all along its canal to the uterus, whose inside was lined with highly vascular membrane. No trace of communication between the cyst and bladder could be detected. In the peritoneal cavity was about a pound of albuminous serum. The preparation is preserved in my museum.

Your obedient servant,

JAMES DOUGLAS,  
Lecturer on Anatomy.

225, George Street, Glasgow,

## SLOUGHING OF THE PENIS AND SCROTUM.

*To the Editor of the Medical Gazette.*

SIR,

A CASE occurred to me upwards of 25 years ago, which made a deep impression on my mind, but as I had never before witnessed any thing like it, nor have I since that time, until within the last few weeks, I was induced to look upon it as one of those anomalous cases which occur so rarely as to throw very little light on general practice. I will endeavour to give a faithful account of the two cases, and I am now disposed to look on them as possessing some degree of interest, and as being perhaps not entirely devoid of instruction. The first case was that of a stout man, aged 30, by profession a teacher of music, residing in a village near Halifax, and a married man of very regular habits; the surgeon who was in attendance informed me that he had seen him, for the first time, on the preceding day, and that the patient informed him that it was only on the previous day that he had first felt some uneasiness in the scrotum; that it very soon became enlarged and inflamed, in which state it was when the surgeon first saw it; he immediately applied a dozen leeches, and afterwards ordered fomentations and purgatives. On the following day I was consulted, being the third day from the commencement, when the whole of the scrotum and penis had assumed a dark red colour, with here and there a black gangrenous spot; the tongue was dark coloured, as in typhus, and the pulse indicated debility. We agreed to give our patient decoction of bark with porter,

and to apply an ale poultice, with lint dipped in melted unguentum resinae flavae. This plan was continued, with the occasional addition of sp. terebinthinae to the ointment, until the whole of the scrotum, prepuce, and a considerable part of the penis, sloughed off. The patient's strength was supported, and in the course of a few weeks he recovered so far as to live for seventeen or eighteen years, when he died, I believe, of phthisis. His death took place some years after I had left that neighbourhood.

The second case was that of a farmer, about 35 years of age, residing a few miles from Ripon, who thought that he had caught cold, which had brought on some itching of the penis and scrotum, both of which, in the course of two days, became very much inflamed and enlarged; on which account he sent for a surgeon, who took blood from the arm, applied fomentations, and gave him purgative medicines. On the following day, to his great surprise and dismay, a gangrenous spot appeared on the scrotum. The blood taken exhibited no indication of inflammation. Before he left the house, I saw the patient with him, and told him what, in my opinion, would be the result, which he could scarcely credit: I then gave him an account of the former case, and, as far as lay in my power, put him on his guard. In this case the tongue exhibited the same appearances as in the former. We gave decoction of bark in the porter, and applied an ale poultice, with dressings, similar to those employed in the former case. The inflammation extended along the abdomen as high as the umbilicus, above which there was an eruption resembling the ecthyma cachecticum of Willan. Suppuration took place above the pubes, the whole of scrotum and prepuce sloughed off, and the patient is convalescent.

During my attendance in the first case, one morning, whilst the surgeon was dressing the patient, the scrotum and penis being in a gangrenous state, a messenger came to request him to go to a woman in labour, who resided about half a mile from our patient, and he obeyed the summons without loss of time. Four or five days after this, on meeting again, he said, "you will recollect that I was sent for to a woman in labour on such a day." I replied yes, what of that? "She is dead; every

thing seemed to be going on well until yesterday, when she was seized with violent pain in the region of the uterus, and she died before I had time to do any thing to relieve her." In the course of two or three days, on meeting again, he said, "It is very odd, Dr. Paley, I have lost another patient in the same unaccountable way as before;" and the next morning, at our meeting, he stated that he had another patient about two miles off seized in the same manner, whom he requested me to visit along with him. After seeing his patient, I told him that she was labouring under puerperal fever, and before we left the house, he was sent for to visit another woman whom he had attended in labour in the same village. I accompanied him, and found her also the subject of puerperal fever. I believe that he had in all six cases of this disease.

I inquired of nearly all the general practitioners in Halifax and the neighbourhood if they had any cases of puerperal fever, but not one could I hear of; indeed, most of the medical men owned that they had never seen a case of it in the whole of their practice. About the same time I was requested to visit a married lady, aged 54, who resided in the same village as the teacher of music, betwixt whom, however, there had not been any intercourse, but she had visited repeatedly the first woman, who had died so unexpectedly. I found that she had been seized, on the day previous to my seeing her, with violent pain of the bowels, which had continued to increase in spite of the means employed. When I arrived she was *in articulo mortis*, and expired before I left the room, which was twenty-six hours after the time she had first felt any sort of uneasiness. In the present day, this case would very probably have been considered as Asiatic cholera; and it is to be regretted that we were not permitted to make a post-mortem examination.

There is not the slightest doubt on my mind that the surgeon who was in attendance was the means of communicating something (call it what you please) from the patient labouring under the disease of the scrotum to the lying-in women, which in them produced puerperal fever; and with regard to the lady last mentioned, the first case of disease after parturition, which in all probability was that of puerperal fever, produced

in her a species of enteritis, which in its progress bore a considerable resemblance to the disease of the music-master.

I pointed out these circumstances to the surgeon, and at the same time advised him to go from home two or three weeks, and to have his clothes washed and fumigated; he did so, and the plague (for such it seemed) ceased. These circumstances I also mentioned to the surgeon in attendance on the case which has recently occurred in this neighbourhood. I advised him to wash his hands well previous to leaving the house of his patient, and not to attend any woman in labour, or after her confinement, without first changing his dress. Notwithstanding this precaution, which I believe he rigidly observed, I received a note from him a few days ago stating that he had had some unfortunate cases of puerperal fever.

I have avoided giving the names of the patients and of the surgeons for obvious reasons, and I shall not make any further observations, but leave your readers to draw their own inferences from the facts which I have laid before them.—I am, sir,

Your obedient servant,

ROBERT PALEY.

Bishopton Grange, Ripon.  
Nov. 26th, 1839.

### CHANCERY CACHEXIA.

ACCOUNT OF AN INDIVIDUAL WHOSE DISEASE AND DEATH WERE OCCASIONED BY THE DELAYS AND VEXATIONS BELONGING TO LEGAL PROCEEDINGS UNDER OUR PRESENT SYSTEM OF JURISPRUDENCE.

By JONATHAN OSBORNE, M.D. M.R.S.A.

Vice-President of the King and Queen's  
College of Physicians.

[For the London Medical Gazette.]

THE following narrative is presented to my professional brethren, not as possessing any new pathological fact, but as well calculated to rouse the attention to similar cases, and to induce them to use their peculiar opportunities of observing such, to inform not only the profession but the public of the extent of an evil which is permitted to exist for the gain of a few; but, which appears to me so enormous and intolerable, that, like any other nuisance, it must be abated as soon as a sufficient body of

evidence, such as the following, is brought forward on the subject.

The diseased state which I am about to describe being without a name, I venture to propose one taken from the most notorious cause of it, on the same principle as other diseases have been named from their causes, as grocer's itch, painter's colic, &c. I therefore suggest that such cases as the following should be called "Chancery cachexia;" but without thereby meaning any disrespect to any of the learned judges, or to the distinguished nobleman who now holds the seals in this kingdom; being well convinced that many of those eminent individuals deplore the existence of the evil, and would gladly remedy it if they did not find themselves bound down under a weight of precedents and tedious forms, which appear to have been invented solely to render the laws ineffective for the protection of property, and to subject those who seek their protection to an unlimited and remorseless system of plunder.

The subject of the following case was a clergyman of the established church, who had passed through an active and useful life in the enjoyment of uninterrupted health. He was, if I rightly recollect, in the 67th year of his age, when I was requested to see him in the beginning of last year. He complained of symptoms which I referred to irritation of the mucous membrane of the stomach, and a torpid state of the bowels, to which latter affection he had always been a stranger. His habits had been strictly temperate, and all his enjoyments were sought for in the midst of his affectionate family, to whom he had been long endeared by the open simplicity and unceasing kindness of his disposition. When I questioned him as to the cause of his stomach affection, he informed me that it was entirely occasioned by a course of proceedings in the Court of Chancery in which he had become involved, and having been appointed guardian to children nearly related to him, he in that capacity was forced into a litigation respecting the settlement of some of their concerns, which had kept him in a state of perpetual anxiety, agitation, and disappointed expectation, for nearly three years previously. I must confess I sympathised with him, having been then above three years myself detained in the Masters' Office in a matter in which there is no

difference of opinion, and which might be settled in three days, and am still kept in it until it shall please the *learned friends* on the opposite side to say that they have got enough—of which I have no expectation, until there is no more to be got. Under treatment, and by a strict attention to diet, he recovered, and was able to resume his accustomed walking exercise for about two months, when I was again sent for. He now complained of cough; his pulse was not excited, and on examination of the chest no other disease was found to exist beyond bronchitis. This yielded to treatment, and I expressed a wish that he should go to the country. This, however, he would not consent to, as the accounts were still uppermost in his mind, and he continued to indulge the hope that by personal attention to them it might be in his power to bring them to a settlement.

In the midst of the awful storm on the night of the 6th of January, a messenger came to say he was dying. I hurried to him, and found him gasping for breath, in a violent paroxysm of spasmodic asthma. On the previous evening he was in his usual health, except that "the law's delay" was observed by his wife to have caused a constant state of perturbation and excitability. By the application of hot water to his hands and feet, a sinapism to the chest, and the use of cordials, his breathing was nearly restored on the following morning, and after a few days he was able to leave his bed. After this, an interval of about a month elapsed, when he complained of cough and dyspnoea. Having ascertained the presence of some crepitus in the right lung, he was bled, and under the usual treatment for pneumonia, in about a week, that, with all the other symptoms, entirely disappeared.

Let it be remembered that all this time the accounts in the Masters' Office were still going on, and that this amiable man, on each recovery of health, was anew exposed to the "hope deferred that maketh the heart sick." His own funds were involved in the cause, so that he had to suffer much inconvenience from the *res angusta domi*. Any reader who has ever been engaged in what is called an *equity* suit, can readily supply what I omit: he can tell how individuals, honourable and estimable in all the relations of life, when engaged *professionally* appear to think them-

selves absolved from ordinary rules of justice\*, and witness the fleecing of those individuals who have been so badly advised as to apply to the law for redress, without any compunction—viewing it as quite a professional and proper thing, making no account of the heart-burnings and macerations consequent on the artful delays and delusive hopes of settlement thrown out; it being a very common result, and one which excites much merriment† amongst them, that besides the loss of the property at issue, both parties, plaintiff and defendant, are dismissed out of court utterly ruined.

My unfortunate patient had returned to the accounts about six weeks, when they began to exercise their most usual and what may be esteemed specific action. His appetite declined, a short cough came on, and gradually increased. He did not regard this with any apprehension, his mind being now occupied with daily expectation of a settlement, which, whenever it took place, he was convinced would enable him to recover his wonted cheerfulness and health. I was sent for, and on being informed of his state, examined the chest, and discovered moist crepitus at the left scapular region, with a want of vesicular respiration in the corresponding portion of the other lung. I communicated to the family my opinion as to the nature of the disease which was now commencing, and in a few days afterwards their alarm was much increased by the occurrence of hæmoptysis. Soon after, his strength rapidly declined, and he was compelled to confine himself to bed. His mind was composed, and he contemplated the probability of a fatal termination of his disease with resignation, and a full confidence in the Divine mercy, but always appeared to labour under the delusion that there was a prospect of a settlement of the accounts in the Masters' Office‡.

\* It is a fact that the celebrated Turpin was a man of unbounded generosity and benevolence. *He only did wrong in his professional capacity.*

† When Mr. Jackson, our envoy, was at Morocco, he was at a fete given in presence of the Emperor. Amongst other entertainments a negro put his head into a lion's mouth. The animal suddenly began to shake his tail, and in a moment afterwards bit the unfortunate negro's head off. Mr. Jackson felt a thrill of horror, and looked round expecting to see the same, but to his utter amazement the whole assembly was convulsed with laughter, in which even the court ladies appeared to join. So far can habit extinguish the feelings of humanity.

‡ Up to the present time, as far as I can learn, there has been no settlement.

His state continued much as I have described, except that considerable alleviation of the cough was obtained, until the end of April, when, during one night, he was attacked with peritonitis, without any known or probable cause: and hence it appears that long-continued disappointment and anxiety had produced in a man, previously healthy in every respect, that peculiar temperament consisting in a combination of debility and irritability which we find only in drinkers of ardent spirits, or in those who have been subjected to a long course of grief and anxiety. The patient gains, in these cases, only alleviation, and never a cure, as the recovery from one attack is usually the signal for the commencement of another in some other, and frequently distant, part. This attack of peritonitis was not severe, but as it did not yield to the first remedies which were applied, I called for further assistance. Sir Henry Marsh concurred in the opinion which I had formed, as to his immediate danger. He suffered less pain than usually belongs to peritonitis in the same degree, but the tendency to sink soon became manifest, and he resigned his breath, in peace and charity with all mankind, within forty-eight hours from the commencement of the last attack.

This case is now stated in order to encourage the statement of similar cases. If it be granted that the legal profession, which differs from most others in being utterly non-productive, should yet continue to absorb almost all the honours of the state, and an amount of wealth beyond calculation, still it is another question, and one which, as affecting the public health, is within our province to discuss, whether some limit should not be fixed to the length of legal proceedings, as well as some degree of certainty and efficacy obtained in their results\*. As long as litigation can be indefinitely prolonged, as at present, there is no security for health or life, any more than for property. Every man is liable to be crushed, according to law, if he happens to have an enemy who chooses to go to the expense of it.

\* I have known cases of the utmost distress in families, and one case of insanity, occasioned by loss of income, arising from the facility which the law affords to persons who extort money by holding possession of houses without paying the rent. To this evil is mainly to be attributed the rapid devastation of those parts of Dublin which have ceased to be fashionable.

In detailing the above case of one who fell a victim to our present mode of carrying on legal proceedings, I conceive that I have not stepped out of my province as a physician, or misapplied the valuable pages of this journal. May the recital of it and of others which are under the daily observation of medical practitioners, rouse the public mind to put an end to what is so deleterious and demoralizing. Those in particular who unite in that solemn prayer, that "peace and happiness, truth and justice, religion and piety, may be established among us for all generations," are in an especial manner called on to inquire whether we, as a nation, can hope to enjoy any of those blessings, so long as a system of chicanery and extortion is permitted to continue; and they are respectfully invited to the consideration of this and similar cases, to see whether a regard for the public health, no less than for the public morals, does not loudly call for its extinction.

---

#### SMALL-POX AND VACCINATION.

---

*To the Editor of the Medical Gazette.*

SIR,

My colleagues in the Vaccination Report here have such an increasing dislike to bestow further notice on the futile attacks made on the Report, that I am induced to relieve them of this distasteful occupation by requesting the insertion of a few remarks in reply to Dr. Gregory's last letter.

It argues well for the excellence of the Report, that the assailants in their efforts to depreciate it find it necessary to have recourse to the unworthy expedients of abuse and misrepresentation. In his last letter, Dr. Gregory no sooner quits his preface than he betakes himself to his old method of misquotation. He gives us three sentences which he has patched up by the aid of transposition and interpolation, and then gravely tells us he does not see the force of the argument. It would be rather surprising if he did, since it is usually necessary that an argument should exist before its force can be seen. But in the sentences, even as they now stand, an argument which confounds common origin with identity cannot be found.

In fact, the fabricating process was not carried quite far enough for this; and whatever confusion exists belongs to Dr. Gregory, for the Report nowhere confounds common origin with identity. The most important doctrine in the Report is, that cow-pox and small-pox (or, as Dr. Baron more accurately designates them, cow small-pox and human small-pox) are the same disease; by which is meant, that the differences which do exist are not of such a nature as to affect their generic identity. The malignant or confluent small-pox, the mild or discrete small-pox, the inoculated small-pox, and the cow-pox, are all different species of one disease, variola. The differences existing between cow-pox and inoculated small-pox are not greater than between the mildest cases of variola discreta and the severest of variola confluens. Cow-pox was immediately recognised by competent and unprejudiced observers as a true variolous disease. Hoffmann says, "This pox surely will secure against the small-pox, being, indeed, nothing else but a real and true genuine small-pox of the mildest sort;" and Soemmering says that they are *morbi non suâ natura sed gradu diversi*. The Report abounds with proofs confirmatory of this truth, drawn from a great variety of independent and unbiassed sources, which the limits of this letter will not admit of my even alluding to. It was never found that the severest and most malignant kind of small-pox gave greater protection than the mildest; and Hoffmann intimates that it was generally believed that one pustule afforded equal immunity with ten thousand, and hence there was a strong presumption that cow-pox would afford equal security with any other species of variola. But do facts warrant this presumption? Does experience bear out another important doctrine of the Report, that the prophylactic powers of small-pox and cow-pox are equal? Undoubtedly, if the just distinction be observed between *having the genuine cow-pox and being vaccinated*. Taking into account the quantity of spurious and contaminated matter that has been in circulation, the gross ignorance of some vaccinators, such as quacks, blacksmiths, excisemen, and nurses (see Report, p. 61), and the culpable heedlessness of others, together with the many impediments to cor-

rect vaccination which so frequently exist, it is likely enough that nearly half of those who have been vaccinated have not had the genuine cow-pox. It was therefore rather a matter of surprise with those who examined the returns made use of in this Report, that the information they contained was so favourable to the opinion of the equal prophylactic agency of cow-pox and small-pox. Wherever the practitioner had carefully vaccinated, and ascertained that vaccination had produced cow-pox, there seemed to be as complete immunity obtained as that which results from an attack of small-pox. The returns, therefore, taken as a whole, together with all the trustworthy evidence before us, amply justified the strongest language of the Report on this point. As to the Report from the Small-Pox Hospital, that was such a damaged affair, it was difficult to know what to do with it. Had my advice been taken, there would have been no need for Dr. Conolly's exposure of it in your last number, since that would have been anticipated by its meeting with a full measure of justice in the Report. I have Sir J. McGrigor's communication lying before me; but as it does not touch upon the point in question, we need not be suspected of suppressing unfavourable testimony. Of course the Section could know nothing of the returns alluded to by Dr. Gregory, since their business was only with documents actually existing. When they appear they will doubtless be allowed their full weight: in the meanwhile each must attach as much importance to the partial account of them as he thinks fit. For my own part I choose to defer the consideration of the tables, and the four great statistical principles, until the returns are published, as I shall then have an opportunity of laying them alongside the authentic documents, as I have done sundry singular misquotations with the genuine text. I could not otherwise be sure that some essential errors had not crept in, as they unfortunately did in the Report from the Small-Pox Hospital, which would effectually vitiate the whole conclusion.

The importance of distinguishing between having the cow-pox and being vaccinated, proves the value of the canon laid down in the Report; the meaning of which is sufficiently clear,

and does not need to be encumbered by any additional clause, as suggested by Dr. Gregory; who surely cannot seriously wish such a canon to be rigidly applied to all cases of secondary small-pox, unless he believes that small-pox scars and the vaccine cicatrix are equally fallible indices.

Dr. Baron's Life of Jenner (p. 278) comes in for a share of Dr. Gregory's peculiar treatment: a phrase is forced to the extreme limit of its possible construction, and then, by wriggling on with little stronger expressions from position to position, a conclusion is at last arrived at, which might lead an unwary reader to think the sentence militated against the Report. A fair examination of the passage would completely destroy the effect of this sophistry. Let the Report also be dealt fairly with; let each one who cares about the matter examine it for himself, without partiality or prejudice. It was an ingenious piece of policy, on the part of the assailants, to attempt *in limine* to throw discredit on the work, and prevent its being read, since it so quietly subverted many of their unsound but long-cherished dogmas. Their efforts have, however, signally failed, and the bitterness and disingenuousness of the attacks will have the effect of drawing attention to the Report; and good will thus accrue to the cause of vaccination from the most untoward and unlikely sources.

I am, sir,

Your obedient servant,

HENRY COLES.

Cheltenham, Nov. 25, 1839.

P.S. Dec. 2.—I had written the above letter above a week ago, but deferred sending it, lest it might cause the attacks and replies to continue to be inserted out of order. I have seen the letters in your last number, but they contain nothing which would make me wish to suppress or alter mine. I have just met with Dr. Conolly, who agrees with me that Dr. Gregory would have made a much better return for that which he professes to feel grateful for, by substituting straightforward animadversions for uncandid strictures, instead of taking leave of the subject on the plea of a courtesy, which looks very suspicious, and with an affectation of forbearance which is wholly uncalled for; since the subject might be discussed without the

writer being assailed, and forcible arguments might be adduced without ungenerous artifices being resorted to. We cannot find in his letter any thing like an explanation of the blunders in the Small-Pox Hospital Reports. It would have been stretching our courtesy too far, to have allowed them to pass muster with us. We can readily believe, and are sorry for it, that they would go down with continental writers, who had not the materials for detecting their inaccuracy; but if Dr. Gregory can really feel flattered by their quoting his errors, we do think Dr. Baron shewed a needless solicitude about wounding his feelings in exposing them. We admit that there is no inconsistency in giving a general assent to the Report, and dissenting from several of the details; but we are still at a loss to account for or reconcile the strain of eulogy with that spirit and mode of depreciation which I have been compelled to animadvert on so often that reiteration must be getting irksome. We congratulate Dr. Gregory on his determination to imitate *Scrutator* by writing anonymously. We commend his prudence, we think he has fallen on his appropriate vocation, and wish him better success in preserving his incognito than *Scrutator* enjoys.

The booksellers here do not distribute your periodical until Monday; and a letter, if its early insertion is hoped for, ought, I suppose, to be sent off by the same day's post, especially if it be long and not expected. The time, therefore, will not permit me to touch upon *Scrutator's* letter now; but if you will allow a little space to notice it, (and particularly the alleged mistakes) in your next number, you will greatly oblige me.

H. C.

*"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."*  
CICERO.

---

## MEDICAL ETIQUETTE.

MR. BANKS, upon whose treatise we ventured to comment in our last article,

has an especial chapter dedicated to the affectation of mystery, which he holds in great abhorrence. It must be confessed, that with the progress of civilization, the professors of every art, from physic downwards, become more communicative. Like the schoolboy who when asked a question, cries out, by way of answer, "That's tellings!" the adept of the middle ages would have given you to understand that the secret which you so rashly wished to share was to him both bread and fame; while the modern student is well aware that the practice of an art does not consist in the dry knowledge of a few isolated facts, but in the exquisite tact with which numerous truths are combined, and brought to bear on a given problem. Such knowledge, if not absolutely incommunicable, is too delicate to be easily imparted; and though it is not impossible to draw a sketch of the practice of physic, yet it cannot be done, like a *Silhouette* portrait, at a single sitting. Hence, as time rolls on, mysteries diminish, and the more cultivated professors of every art clearly see that they are not in danger of being reduced to the level of the multitude, or even of raising the unskilful to their own, by giving plain answers to plain questions. To be perfectly impartial, however, it must be allowed that the question asked is often not so plain as the querist supposes, and he is startled, in consequence, at what he imagines to be the learned prolixity of the answer. He has said, "Open, Sesame!" to the gate of knowledge, and is rather astounded than pleased by the accumulated treasure within. Swift says, in his biting way, that a farmer will tell you in two words that he has broken his leg, while a surgeon, after half an hour's discourse, shall leave you to seek. Now, after allowing something for the old, formal, and scholastic style in fashion 150 years

ago, we must attribute still more to the surgeon's wish to define the precise nature of the fracture. The former knows that he has got a bone in his leg, but does not know that he has got two; while Swift's surgeon, expatiating over the ample field of fractures, simple and compound, of tibia, fibula, or both, forgets that he is casting his pearls before swine.

This reproof of the Dean of St. Patrick's is a proper introduction to Mr. Banks's first point in the chapter on the affectation of mystery, as he begins by reproving medical practitioners for using technical terms in the presence of their patients. He has "heard physicians use such words as 'secundum artem, ad deliquium, toastum boastum,' &c. &c. when talking to a general practitioner before others: such can only impose upon the ignorant, and cannot fail to lower a man in his own estimation." Now, whether "toastum boastum" belongs to some burletta at the Surrey Theatre, or is a drop from Mr. Banks's own peculiar vein of plesantry, we have nothing to say in its favour; and very little in defence of "secundum artem;" but "ad deliquium" stands upon a different footing. It belongs to the class of euphemisms by which we endeavour to throw a veil, however transparent, over an unpleasant idea; and as the ancients said *obiit*, and not *mortuus est*, so the moderns often prefer "I bled her *ad deliquium*" to "I bled her till she fainted;" In other cases, the technical term is justified by its brevity. It sounds better to say "we found a scirrhus in the duodenum" than "we found a hardness like white India rubber in that part of the small guts which joins on to the stomach." If the physician, when addressing the general practitioner, intends the laymen present to understand his discourse, it will become necessary to melt down

half the terms of anatomy and physick into definitions.

But a more comprehensive question suggests itself to us:—"Would it not be better, ninety-nine times out of a hundred, to refrain from medical discussions in the presence of the laity?" When the rare occasion arrives, the bystanders will forgive the doctor who has no extempore translation for *duodenum*, or *æna portæ*, or *torcular Herophili*; but in the other ninety-nine instances, the fault is not so much in using technical terms, as in persisting in a conversation which renders technical terms necessary. Mr. Banks was once so unfortunate as to dine at the same table with a lawyer, "who, amongst many other professional terms, said, 'nothing was so mean as a *tu quoque*;' " and he thinks that "if this gentleman could have seen how ridiculous he appeared, his countenance would doubtless have betrayed some embarrassment of the internal man." This *tu quoque* would seem to have been the last drop that made a whole cup of law-Latin run over, otherwise there is nothing so intolerable about it. Indeed, we should not have suspected it to be a technical term, but should have classed it among those harmless phrases likely to be understood by all the braceate portion of the company, though coming under the general prohibition of "no Latin before ladies." Our readers will note, however, that though in one point we are more tolerant than our surgical Mentor, and have a less intense horror of two words of Latin, yet, on the other hand, we disapprove of the too prevailing custom of forming a little professional knot in the middle of a mixed party, and turning it into a medical debating society. Our younger readers will do well to avoid this practice, as well as the one of giving a medical lecture, with or without the excuse of a question asked. Such professional

wordiness will be unfavourably interpreted (though perhaps sometimes unjustly); it will be thought either that the offender is deficient in the ordinary knowledge of an educated man, or that he has resolved to make all his visits so many advertisements.

A kindred subject to the use of technical terms in conversation, is the question in what language prescriptions should be written; but this topic has been strangely banished from the chapter to which it belongs, and transported to one on minor points, "about which there seems to be no general understanding, and, it is to be hoped, there never will, as they are quite unworthy of notice." The question, as stated by Mr. Banks, is, "whether prescriptions should be written in English, Latin, Greek, or double Dutch?" Now a prescription in single Dutch, the language of Amsterdam and Leyden, would sorely perplex most of the druggists we have come across; but what they would say to one written in double Dutch, a language the very quintessence of unintelligibility, and spoken probably in Laputa alone, we hardly venture to guess. Nevertheless, we think it probable that a few prescriptions written in this tongue, and in Greek, would drive our pharmacutists to despair; and we therefore esteem it fortunate that practitioners in these islands *have* come to a general understanding, and always prescribe either in Latin or English. We suppose, however, that the real doubt which Mr. Banks means to hint at under his veil of humour, is, whether it is better to use Latin or English on these occasions. Now far from thinking this point one unworthy of notice, we deem it well deserving of discussion, and are of opinion, moreover, that it would have been perfectly germane to a treatise professedly on medical etiquette. The

practitioner may have remarked, that both in France and Scotland the Pharmacopœia is in the language of the country (indeed, in France, physicians were enjoined by Napoleon to prescribe in French, with the intention of diminishing the probability of mistakes); and he may naturally ask, whether it would be permitted him to order medicine in England in his native tongue. He would not be a little surprised to learn, that although Mr. Banks finds room to denounce electors who vote against their conscience, and appeals to the medical profession to take under their care "the glimmering embers of morality," which are not likely, it seems, to be fostered either by the church, the law, or "the Educator," yet he has nothing to say on this delicate difficulty. If we were allowed to give an opinion upon what ought to be, we should say that the safest plan for the practitioner would be to continue to write the mass of his prescriptions in Latin, according to the existing etiquette.

Another affectation of mystery censured by Mr. Banks, is the practice of disguising medicines, as, for instance, mixing rose pink with linseed meal, or vermilion with Epsom salts. This is half mystery, half trick, and we agree with him in condemning it. The only modification of this plan of adding any thing to change the colour at all admissible, is the one which which was some time ago suggested, of having oxalic acid always tinged of a particular hue, to distinguish it from sulphate of magnesia.

The other practices censured in the same chapter are simple tricks, and do not come under the head of affectation of mystery. Among these are the being called out of church, and "riding hard by when people are coming out, his horse

foaming and sweating—poor animal! all in the cause of falsehood." As to the trick of being called away from church, dinner, or the play, it is one of those which have become so stale, as to be a matter of trite observation among the laity; so that, at present, a genuine calling out has more chance of passing for a false one than *vice versa*. Mr. Banks, indeed, goes so far as to reckon the being called out from church and other public places, together with the galloping, as nearly obsolete; perhaps, therefore, in due time they may be revived by the skilful; there is nothing so new, say the French, as what is forgotten. Some, again, if they should happen to get a Lord upon their books, make his name more common in their conversation than the definite article. Another man could not open his mouth without revealing the fact that he kept "a horse and chaise." A bet being accordingly built upon this weakness, he was asked what o'clock it was; and he answered, as by habit bound, "When I passed the Horse Guards this morning in my horse and chaise, it wanted," &c.

Some practitioners, says the accusing Banks, send medicines to the wrong houses, by a wilful mistake, as each explanation is an advertisement. We never heard of this before, excepting in the *Pickwick Papers*, where Sawyer, late Kuockemoff, tricks the public after this fashion; yet we suppose all that is *do-able* is done. Mr. Banks disapproves of the fashion of appending letters to men's names as a sign of their possessing some unimportant office. We recollect that Mr. Babbage, in his work on the decline of science in England, gave a list of the most dignified capitals which commonly follow authors' names, with the prices paid for each; "those," he added, "who are ambitious of scientific distinction, may, according to their

fancy, render their name a kind of comet, carrying with it a tail of forty letters, at the average cost of £10.9s. 9½d. per letter." The particular combinations mentioned by Mr. Banks, G.U.L. or T.O.P., must be much cheaper.

The next points censured (and always under the head of affectation of mystery) are the keeping patients waiting longer than is necessary; the claptrap of writing up *advice gratis*; and the custom which some physicians have of sending all their prescriptions to a given shop, where they have a share of the profits. This share, too, is under the rose; if it were openly avowed Mr. Banks would not censure the custom.

He finishes his chapter by stigmatizing the servile suppression of our own sentiments, and the abstaining from all opinion on public subjects; and brands those who do not go to the poll at an election, as guilty of a flagrant dereliction of duty, and those who vote against their convictions as monsters of iniquity, with many more hard words. Now, we should be the last persons to defend shufflers, skulkers, or vote-sellers; but we somewhat doubt whether this work was the place for their castigation. It is like erecting a pillory in a flower-garden.

#### THE PROPOSED "SANATORIUM."

WE perceive from reports in some of the papers that Dr. Southwood Smith, Dr. Arnott, and some other gentlemen, have it in contemplation to establish, under the name of "Sanatorium," an institution similar to some of those in Paris, where patients are provided with board and medical treatment on the payment of a certain sum per week. In France such institutions have answered very well, but there are various circumstances which, we suspect, will

prevent their success here. In the first place, the plan is contrary to the genius of the inhabitants of this country; none who can contrive, by any means, to remain at home, will voluntarily change their residence, or consent to be surrounded by strangers, in the hours of sickness, if they can manage even at some sacrifice to have attendance in the bosom of their own family. Again, the experiment has already been tried in London, we believe, very fairly, and has failed. An institution, on what we understand to be the principle of the Sanatorium, was established at Lisson Grove, under very active and influential patronage;—Mr. Holland, of Montagu Square, Sir William Pepys, and other philanthropic individuals, having, although unavailingly, devoted a great deal of time and pains to insure its success. The plan was to have accommodation for from 30 to 40 patients, who were provided with good board, lodging, and medical attendance—the women for 12s. and the men for 14s. a week, the rest of the required income being made up by annual and other subscriptions. The institution, however, was strongly opposed by the general practitioners, and progressively drooped, so that it was necessary to raise the terms to 14s. a week for females, and 17s. 6d. for men. Even with this increase, however, we understand that the proceeds never nearly equalled the expenditure, and, at the end of some years, it was found necessary to break up the establishment altogether.

We doubt much whether any institution of the kind will ever succeed here. As we have already observed, it is not well suited to the habits of the people, which are essentially domestic; while the circumstance of their paying at all, makes patients very exacting, and difficult to please. Besides, though one or two such establishments might be little

felt in a metropolis like London, yet the principle is certainly inimical to the interests of the general practitioner, and hence gentlemen in this branch of the profession will naturally view it with dislike, and, with their opposition, it is not possible for institutions of this nature to succeed.

We anticipate, as most probable, that the parties who have set about the Sanatorium will abandon the scheme before it has been brought into actual operation; or, if established—like the similar attempt at Lisson Grove—it will linger for a short time, and then be discontinued for want alike of patients and of friends.

---

#### THOUGHTS

ON THE

#### NEW UNIVERSITY AND THE COLLEGE OF SURGEONS.

---

*To the Editor of the Medical Gazette.*

SIR,

THE following strictures originated in the wish of a friend, that I should communicate to him, by letter, my opinions on the present extraordinary position in which the College is placed. As I have stated the circumstances that seem to me to explain the relative position in which the University and the College stand towards each other, I thought they might, with advantage, find a place in your journal; and if you think so, I shall be obliged by your inserting them.—I am, sir,

Your obedient servant,

C. ASTON KEY.

Nov. 30, 1839.

Dear —, you have often asked me whether I consider the College of Surgeons, and our other medical institutions, to be so perfect, and their present position so satisfactory, as to need no improvement, and what my opinion is of the Medical Association. To the latter part of your question I can at once reply; that the proceedings of the Association bespeak so much political partizanship, and so much questionable

feeling, that though I approve many of its objects, I do not incline to enlist in their corps. The second part of the question, touching the condition and prospects of the Royal College, shall have an equally distinct, but more explicit answer; and you must bear with me, while I endeavour, briefly as I may, to point your attention to the circumstances by which the College, as well as the other authorities of the profession, are placed in their present anomalous attitude. You will remember that these strictures come from the hands of a friend to the College, who can have no motive in making them but a sincere desire to see its dignity upheld by the united voice of the profession.

It matters but little to the question how far a University in London was, or was not, a desideratum; it is enough for us to know that it has been founded, and it will sufficiently answer my purpose to advert to the circumstances that attended its formation.

We must go back as far as the year 1826, or thereabouts, when the project of establishing a University in London was first talked of, to include among other sciences that of medicine. It seemed reasonable as well as expedient that this metropolis, possessing as it does the means, should be invested with the power of conferring academic honours and degrees in medicine and surgery, and thus be placed on a footing with the other capitals of Europe. The material for a University seemed already to exist in the large medical and surgical schools of London; and the project of forming a University appeared to afford a good opportunity of uniting the schools of anatomy, and placing them on a University basis; I endeavoured to draw the attention of some influential members of the profession to the subject. With this view I drew up a sketch of what seemed to be a feasible plan for effecting this object, and forwarded it to two leading members of the College of Surgeons, whom I knew to have at heart the welfare of the profession, and to possess the judgment to decide what was best for its interests.

What difficulties existed at that time, in the way of uniting the schools and the College with the contemplated University, I cannot say; no attempt, that I am aware of, was made to effect

so desirable an object. The College remained supinely waiting for events, instead of anticipating and directing them; and the opportunity thus let slip was quickly seized by other and more active hands. Possibly the original projectors of the University might have been averse to any connexion with the existing institutions; an objection which the constitution of the College renders highly probable.

At first they attempted to obtain for the University College, as it is now called, a charter with the power of granting degrees, and thus to constitute this small section a University. This attempt to invest a school with the powers of a university failing, as it well might, a powerful influence, strengthened by the result of the parliamentary medical investigation, was exerted with the minister of the crown; and with his aid, in the teeth of the Royal Colleges of Physicians and Surgeons, and the Company of Apothecaries, an institution has been founded that threatens to surpass these bodies both in powers and in importance.

Small as the beginning of the new University is, it needs no great foresight to see that it contains the germ of future greatness, and if properly cultivated, its stature will be commensurate with the acknowledged wants of a large body of the profession. One fountain of honours, that is, a University, does seem to be wanted; something beyond a diploma or a license to practise is looked for by a large body of practitioners; and that something it is not in the power of the existing authorities to grant, unless they undergo some modifying changes, and meet the wants of a large and respectable part of the profession.

The new University, so far as a degree is concerned, does supply this want, imperfectly it may be said; and also places London on a nearer footing with other capitals. The circumstances that attended its formation are not calculated to place it very high in the estimation of the profession, nor to render it at present a very formidable rival in the eyes of the Council of the College of Surgeons. Its birth may be considered suspicious, springing as it does from a spurious source, the spirit of party. Professors there are none; and the Senate, with its Board of Examiners,

number amongst its ranks but few of the *élite* of the profession; nor does the mode of election seem to accord with that purity of which so much is spoken; the minister, it is said, with the aid of parliamentary advisers, has made the chief part of the senate nominations, and the selection of examiners from the senate has not met with the cordial approbation of several of its members. To all these objections, however, it may be reasonably answered, that the University is in its infant state; that an elective body is not yet in existence, and that the chancellor or minister was obliged to get together the best senate he could, under the circumstances that ushered the University into being. Its position, too, prevented a selection of anatomists and surgeons being made from the Council of the College, or from the leading teachers of the schools; and the inexperience of the examiners has hitherto prevented the examinations from being quite as satisfactory as could be wished.

Many more objections might be urged, and many disadvantages stated, under which the University must be allowed at present to labour. The infant University, however, still possesses so much promise of future vigour as to well deserve the attention, if not to excite the apprehension, of every well-wisher to the College. Its strength is in the hold which, under good management and judicious government, it cannot fail hereafter to acquire over the mass of the profession. Supposing, and any other supposition would be idle, that the election to the senate should be hereafter thrown open to all its members, and that every member when admitted may entertain the hope of being called, at some future day, to fill the respectable post of a member of the senate and board of examiners; such a law would at once attract the larger part of the professional talent of the country; candidates of a high grade would become competitors for the distinctions which the University has to offer, and in a short time the University would become the popular institution of the country. Some such measure will assuredly be adopted by the University, and then every objection that can be made to the present constitution of its senate and examiners will be overcome by the encouragement held out to the profes-

sional talent of the country, and the banishment of that system of exclusion that prevails in the other governing bodies of the profession. An elective body of talent and influence will gradually be accumulated, and a proportionate weight and importance will be imparted to the whole body of the University.

Admitting, however, that the want of first-rate professional talents and character in the examining body should fail to render the degree an object of ambition to the profession—a circumstance that in its infancy is not improbable—or that any other cause should tend to retard its growth; its very weakness may operate to its advantage. Its chancellor has only to appeal to the government that founded it, to picture its unprosperous condition, and to request more privileges and more power; and to such an appeal it is not to be supposed that the minister will turn a deaf ear. He is in some degree pledged to its success, and will do all that he reasonably can to ensure it. If the University, seeing that its degrees are not valued, ask to be placed on an equality with the Apothecaries' Hall, and to have the privilege of granting along with its degree a diploma or license to practise medicine in all its branches, is it probable that such power will be denied to them? They will plead that the medical examiners of the University are persons in every respect as fit to be entrusted with the general medical education of the country as the examiners of the Apothecaries' Company; and who can deny the justice and truth of the plea? Equal powers will assuredly be granted to them, and when once the license of the Hall is supplanted by the University, the College, not possessing the power to compel an examination, will find, that the student will prefer one examination and one fee, and that its diploma will have but few candidates. If the College continue to rest its claim to the support of the profession on its present grounds, a few years only will suffice to work this change.

The Council of the College may possibly regard such apprehension as chimerical. Those in power are often blind to danger that others see approaching. I do not, however, believe that the leading members of this body can view the University with unconcern,

or that they are insensible to their present position. They may possibly regard the infant University as insignificant, when compared with their own body, in point of resources and present importance. The history, however, of every institution of magnitude in this country, with few exceptions, will tell how small a beginning they have had. A seed sown in a fertile soil is sure to be well nurtured, and to flourish. If an association in this liberal and wealthy country be judiciously commenced, meeting the wants of, and finding favour with, the public, funds flow in to its support, time brings friends, talent comes to its aid, and what at first was a small institution becomes in time a largely endowed establishment. This is the history of all our charitable and scientific bodies, and the new University is not likely to be an exception to it. It brings to its support the powerful aid of government; it does not depend wholly on, though it needs, the countenance of the public; it supplies, in some measure, a want that has been long felt. It appeals strongly to a large discontented body in the profession, who will not withhold their support, and has to compete with institutions from circumstances, not want of talent, enjoying but a small share of popularity. Its ultimate success may be reasonably expected, though its present unassuming position may excite no feeling of apprehension or jealousy.

Not the least striking circumstance attending the formation of the University is the entire silence of the profession, and its quiet acquiescence in the indirect encroachment on the privileges of the College. Scarcely a voice has been raised against the powers granted to a body in which the leading surgeons of the country are not included, and in which the College of Surgeons takes no part. The indignity, if such it can be considered, offered to the College, is not resented by its members; as if the College and its members had no common bond of attachment. This anomaly is only to be explained by the peculiar constitution of the College, and the equally peculiar position of its members.

The council and examiners, it must be admitted by all, contain some of the most respected names in the profession; and if one or two members of lower pretension have been occasionally admitted

among them, they form the exception to the rule. Their examinations have been conducted with due regard to the education of its members, and with leniency to the candidate. The Museum has been nobly preserved, arranged, and enriched, at the expense of the College. Lectures have been instituted; and its legislative measures have been, with few exceptions, such as tend to uphold its character as a scientific body. Through ill and good report they have endeavoured to discharge their duty, according to their charter and their laws: and yet, can it be said that the College is popular with the profession? The members, it is true, seek to obtain its diploma, because without it some public appointments cannot be held; and, till lately, no other chartered body has had the power of conducting surgical examination. The degree of popularity that it does enjoy is owing to the individual weight of one or two examiners, and not to the whole as a body. Is it popular with the country? The answer is, that a petition to parliament for such powers as had been granted to the Apothecaries' Company was made, and refused; and the profession saw in silence the failure of the application. On occasions when the proceedings of the College have been assailed without regard to truth, and misrepresented and distorted to serve party purposes, not a voice has been raised in its defence. The Royal College of Surgeons is sometimes pledged as a toast at a public dinner, but more as a matter of form than of feeling; and then something cold is said by way of compliment, and something as cold replied by a member of council, as the expression of thanks for the honour conferred; its prosperity excites in its members no feeling of pride, as its degradation would none of sympathy.

Why is the College, with its talent, respectability, and great resources, regarded by the profession with so cold, so jealous an eye? It is, because the members have no community of feeling with the College. The student, when he becomes a member on receiving his diploma, and leaves the door of the building, feels that he has no closer connexion with it than before his name was enrolled. He asks himself, and asks in vain, what advantage he derives from the fee that he has paid, and from

the severe self-imposed examination that he has undergone. His hopes and fears, once centred in the College, end with his examination. In truth, he can hardly be said to have any connection with the College. If he chance to live in London, he may hear, if he please, an occasional lecture, and may have access to the library—advantages that his former school of medicine still continue to afford him. It is no *Alma Mater* to him. He may long for its honours, but they are beyond his grasp; he feels that no industry, no exertion of talent, can place them within his reach. As he advances in life, he sees his former fellow-student, possessing half his industry, talent, and knowledge, called to the council of the College, from which he is excluded, and raised to the rank of examiner, which he never can attain. He has no voice in the election of the council, much less in its measures; he feels himself a cypher, if not an alien, and that he is so regarded by the College. Surely there is nothing in this system to attract, but every thing to alienate from the College, the affection of its members.

The faulty system which the new University has adopted in the choice of its senate and examiners, the College continues to practise. The University has the excuse of possessing yet no academic body, from which the election can emanate: the College has no such excuse; its body is large and well educated; and the only palliation for their proceeding is long established custom. By what rule a member is elected to the council, I do not exactly know. To be a London surgeon, and not to be a general practitioner, seem to be two of the necessary qualifications. He need not be a surgeon to an hospital, for persons are selected who are known only as private practitioners. He need not be a surgeon of high professional reputation, for some are of the council whose scientific attainments will not bear a close scrutiny. There is a conventional rule, I conclude, not well defined, but sufficiently understood, to guide the election of the members of the council. Thus entrenched, the governing body of the College knows that it is not popular, and endeavours to atone by legislation for the defects of its system. The exclusiveness that prevails mars their best intentions, leading to all

kinds of evils, both to their own body and to the profession; among others, to measures of doubtful policy in order to conciliate popular feeling. The two last alterations in the laws of education will illustrate what I mean. One is, the abolition of apprenticeships, and the limitation of the period of study to four years. Those who brought forward such a law must surely have forgotten how much, or rather how little, they themselves knew at the end of four years; that the increased severity of their examination requires rather a prolonged than a curtailed period of study: they might also bear in mind that it takes as much time to make a good surgeon as it does to make a good carpenter. But for this error there is an excuse, as it would seem to be only a show of liberality; for the law is wholly inoperative, while the Hall retains its period of apprenticeship. The other is, the committing education wholly to provincial schools. It cannot be said that either of these measures is calculated to raise the standard of education; but they are both popular, and so far answer their purpose. One is probably intended to conciliate the good will of students; the other, that of provincial surgeons; and the end is thought to be gained. The policy is shortsighted. The council cannot suppose that the obvious inference from their own law is overlooked by provincial surgeons; namely, that if their schools are qualified to conduct the whole of education, and to be placed on an equality with the London schools, the leading provincial surgeons ought to be placed on a footing with the London surgeons in respect to eligibility to the council: and why should they not? Besides, all these small acts of legislation, as expediency may drive, cannot have a lasting good effect: they have the semblance of liberality, but not the substance. The surgeon and the student still remember that they are excluded from the honours of the College, and, forgetting the boon, think only of what is withheld from them.

To meet the coming difficulty, the College has three modes of proceeding, and it will be seen by the measure they adopt what their view of their present position is.

They may apply at once to parliament to strengthen their powers, and to make

the examination, which at present is voluntary on the part of the student, compulsory. If this power be granted, the College may think themselves secure from all encroachment on the part of the new University. And so they will be, if the privileges of the latter body remain as they now are; but if these also are enlarged, and if their reputation increase with the increase of their academic body, the student will prefer the one fee, the license and degree of the University, to the double examination and the double fee of the College and Hall. It remains, however, to be seen whether parliament will grant to the College, with its present unpopular constitution, an extension of its privileges.

Another line of policy is, to wait the tide of events, and the demolition of the frail fabric of the University. Temporalizing policy may induce the College to look for a change of ministry, in the hope of seeing the University crumble away with the powers that created it. The wisdom of such proceeding, however, may be doubted.

A third course, by which alone its strength can be permanently increased, is to rest its claim for support on the attachment and esteem of its own members. This can only be done by allowing to each member a vote in election of the members of council. Such a measure would make the College what it has not yet been—a representation of the whole body of surgeons, instead of being, as it now is, a small self-elected section, taking into its own hands the management of its internal concerns, and the legislation for the whole of the profession. The council and the members would form one powerful body, acting in unison, for the common good; the feelings of the members, now diverted from the College, would be concentrated towards it. They would join in measures for its advancement, and in defending it against attacks, which, if made, would then be few and feeble, honourable ambition would be encouraged; and those who work for the profession would replace those who do nothing for science. The libeller would be silenced, and the discontented would be satisfied. Thus strengthened, the College might apply with confidence to parliament for any reasonable extension of powers. The council would

then embody the surgical talent of the country in a most popular form, and would have little to fear from the success of the University. In what position it would stand in relation to the University it is not difficult to see, as the best surgeons and anatomists would be anxious to belong to the council elected by the common voice of the profession.

It is not easy to understand by what arguments, or on what grounds, the College can refuse this boon to its members, if the petition were properly preferred; nor how it can retreat from its own admission, that the provincial schools are fully qualified to conduct surgical education, or from the obvious inference, that they are also as well qualified as the London surgeons for the less important duties of the council. The great difference in point of education and acquirement that formerly existed between the members of the council and the provincial surgeon, is allowed by the College itself no longer to exist. Even in past times a Park of Liverpool, a Hey of Leeds, a White of Manchester, and a Dalrymple of Norwich, would not have disgraced the council of the College; and many provincial surgeons might be named who would grace the council board to the full as much as many who now sit there. The privilege of voting is also due to the members, who are supposed to be well-educated and well-conducted men. I say supposed, for if they are not really so the fault lies with the council, who direct education, and with the examiners, who test its fruits. It is a part of the duty of a governing body like the College, so to legislate that a sound moral as well as professional education should have been given to the candidates for its diploma; and so far it is bound to render its members qualified both to judge properly of professional reputation and acquirement, and to exercise a sound discretion in the choice of the members of council. An intercourse of some years with members of the profession persuades me that they are so qualified, and that the honour of the College and of the profession may be safely entrusted to them.

Objections that will be urged against such a measure are such as are made against popular elections in general. An election of members of Council by a learned body cannot be termed popular in

the objectionable sense of the term. A popular election is defective from the passions or interests of the electors giving them an improper bias, or from ignorance of the qualification necessary for a member of Council. The interest and feelings of the member would be identified with the College, and no improper motive would be likely to interfere with a sound exercise of their privilege.

It might also be objected, that the editor of a certain journal, who has always shewn himself hostile in the extreme to the College, would be elected, would subvert all rule and order, and sacrifice the interests of the College at the shrine of popularity. No one person if elected could do so much mischief as this; nor indeed is it likely that he would be chosen by the profession. Nor if elected is it probable that he would accept an office for which his pursuits of late years have not qualified him. Whatever his original fund of professional knowledge may have been, subsequent experience and practice have not added much to it; and possibly it may have undergone no inconsiderable diminution, even to a certain algebraic sign, that ill qualifies a man for an examiner in anatomy and surgery. His known utilitarian principles would at once prompt him to decline the honour, and to release the Council from the terror of his presence. In order effectually to prevent any really objectionable member being elected, the College might retain a *вето*, that would act as a check on the electors, even though it should not require to be exercised.

It may be said, that the leading members of the profession would not submit to the annoyance of a canvass and a popular election, and would not come forward as candidates; while men of doubtful pretension, by force of intrigue and noise, might be preferred. It might be so ordered that the names of candidates should be laid before the profession for the period subsequent to the last election, in order to give time for the relative qualification of each to be ascertained. I am far from intending to lower the standard of qualification for a member of Council; on the contrary, my wish is to raise it; nor am I at all desirous of depreciating the character of the hospital surgeon, as I cannot be insensible to the opportunities that surgeons long connected with hospitals pos-

sess of cultivating the science and practical part of the profession, and of qualifying themselves in a superior manner for the discharge of the duties of an examiner. If surgeons of hospitals do their duty towards the profession, by improving its science and raising its character, the profession in return will not fail to elect them, as the fittest persons, to the Council of the College. But this fitness, I say, let the members determine.

Other advantages, to be expected from such a change, are not few nor unimportant. The present want of exhibitions will probably be supplied; a motive for enriching the funds of the College, for such an excellent purpose, will then exist, and generous individuals will be prevailed upon so to apply their redundant means. It is probable that it will also have a good effect on the literature as well as the tone of the profession. Crude works, hasty opinions, ill digested theories, and imperfectly tested modes of practice, will more rarely issue from the press, as they will fail to produce that lasting good impression, which will then become more the object of active and intelligent surgeons.

A change of measures in any society usually inflicts injury on some; and a change in the mode of election of the Council will not be without its consequences to those who, like myself, look forward, in the present course of events, to become members of that body. The Council itself will not suffer by the change, and the members generally will benefit by it. The expectants, under the present system of election, will be the only sufferers. I cannot presume to say what their feelings may be, or how far they may coincide with the view I have taken of the matter; I have no right to prejudge nor to attempt to influence their opinions. They are at least as well qualified as I am to judge of the matters here discussed.

In the view that I have taken of the matter, I am only following in the wake of the College. Some measures evincing a desire of conciliating popular feeling have lately been passed; and, as a well-wisher to the College, I am only carrying out their own principle, in shewing the consequences to which it inevitably leads. Their late enactments are possibly the shadows of coming events; either they are the forerunners

of a more substantial grant to the profession, or the College is blind to the consequences of its own legislation.

I find that my remarks have reached a greater length than I at first expected. The subject is too important a one to be fully treated in a letter. I shall, however, send this sketch, imperfect as it is, to the *MEDICAL GAZETTE*, with a request to insert it in the forthcoming number.

Ever yours sincerely,

C. ASTON KEY.

## ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Nov. 12, 1839.

SIR B. C. BRODIE, Bart. President, in the Chair.

THIS being the first meeting for the season, it was very fully attended. We subjoin abstracts of the papers read.

*Case of Strangulated Hernia, in which the Bowel was ruptured by the Patient, in his efforts to reduce it.* By BENJAMIN TRAVERS, F.R.S. Senior Surgeon to St. Thomas's Hospital.

The patient in this case was a strong and active young man, 20 years of age, and had been from his birth the subject of congenital hernia. Having always been able to reduce the swelling by lying down and gently pressing it with his hands, he had concealed the existence of this infirmity altogether from his family. On the occasion here described, however, he had not been so fortunate; the hernia had descended in the afternoon of the day preceding that on which he was seen by Mr. Travers, who thus describes the course of events: "Upon inquiry I learned, that at six o'clock of the preceding evening, the volume of the tumor became so increased as to oppose a resistance to its return, which the young man could not overcome. In addition to continued violent manipulations, he compressed it forcibly between his hands and thighs, and, as if reckless from ill success, actually made a section of the integuments with a razor transverse to the cord." The author first saw him at three o'clock on the following morning, when he was pulseless, with livid lips, and other signs of approaching dissolution. The scrotum was enormously distended and of a sanguineous hue. Having given the patient some warm brandy and water, Mr. Travers proceeded to operate, when on opening the sac and handling the parts, the protruded bowel

slipped into the belly without its being necessary to enlarge the ring. The patient lived three hours after the operation, when it was found, on examination, that a portion of the lower third of the ilium, equal to a hand's-breath in extent, presented the appearances of recent strangulation, accompanied with laceration and extravasation of blood between the peritoneal and muscular coats. The mesentery was stripped from the intestine to the extent of an inch, and an irregular aperture was formed in the bowel to the same extent.

*Case of Uterine Hemorrhage, in which the blood escaped through the Fallopian Tubes.* By W.F. BARLOW, Esq. (Communicated by Dr. M. HALL.)

A young woman, twenty-two years of age, who had miscarried at the sixth month, with much flooding, had an attack of purpura hæmorrhagica, from which she died five days after abortion had taken place. On dissection, a quantity of blood was found to have been effused into the abdomen and pelvis, some of which was coagulated; and, as clots were found projecting from the fimbriated extremities of the fallopian tubes, from which, as the author considers, it was evident they had been expelled, he infers that uterine hæmorrhage had taken place through these tubes into the abdomen. A preparation of one of the tubes, having a lobulated coagulum projecting from it, was shown to the meeting, together with a drawing from it when recent. The uterus was less than the size it generally assumes a week after delivery, and a coagulum of blood partly occupied the neck of the organ.

Nov. 26, 1839.

*Dr. Burne's Three Cases of Gastritis.*

In consequence of suggestions for employing the arsenious acid in substance in the form of a pill, rather than the arsenical solution, in menorrhagia and other uterine disorders, contained in a paper read in 1838 before the Royal Medico-Chirurgical Society, Dr. Burne administered it in pills, containing each the 20th part of a grain, to a young lady, under menorrhagia, without any unpleasant effects. In a second case, a young woman, who had suffered from amenorrhœa for nine months previously, took a similar and equal dose on Thursday, two doses on Friday, and one on Saturday. On the evening of Saturday symptoms of inflammation in the stomach came on, which, after some subsidence, recurred twice; on one occasion

with delirium, palsied shaking of the head, swimming of the eyes, and such debility and exhaustion as to place life in imminent danger—"a result so disastrous," says Dr. Burne, "that I thought the details might be useful as a caution to others who may be disposed to administer arsenious acid in substance. For myself, I shall hereafter abstain from prescribing it in this form."

The next case was one of spontaneous and idiopathic mucro-gastritis, fatal in fourteen days, probably preceded by chronic disease of the muciparous glands of the stomach, of which a considerable portion exhibited them of unusual size and appearance.

The last case, also spontaneous and idiopathic, was one in which Dr. Burne considers the symptoms to have shown that the inflammation was seated in the sub-mucous, muscular, and subserous tissues of the stomach, and which he compares and contrasts with the symptoms of the case immediately preceding.

*Observations on the Corpuscles of the Blood and Pus in certain Animals.* By GEORGE GULLIVER, F.R.S. &c. (Communicated by JOHN G. PERRY, Esq.)

The author, remarking that at an early period of his inquiries he entertained, in common with many other pathologists, the hypothesis of the transformation of the blood corpuscles into those of pus, relates summarily the result of many experiments which he has made on them in various animals; from which it results that the former are very variable in size, and that the latter differ in this respect so remarkably, that their magnitude in any single experiment, as compared with the size of the blood corpuscles, is of very little value in regard to establishing any relation or difference between these bodies.

Now, the interesting observations of M. Mandl on the blood corpuscles of the dromedary led the author to examine them in the paco (*Anchenia paco*), Llama (*Anchenia glama*), and Vicugna (*Anchenia vicugna*), in all of which he has found the blood-discs to possess a very distinct elliptical figure; and having had an opportunity of examining a small quantity of pus from the latter animal, the author found its corpuscles to be clearly spherical, and possessing the characters, in fact, of pus globules obtained from many mammalia with circular blood corpuscles. Hence, without denying the possibility of the transformation of the blood corpuscles into the globules of pus, the author remarks that such change could hardly have taken place in this instance.

*On White Spots on the Surface of the Heart, and on the Frequency of Pericarditis.* By JAMES PAGET, Esq. (Communicated by J. G. PERRY, Esq.)

The object of this communication is to prove the inflammatory origin of the opaque white spots so commonly seen on the surface of the heart, by the fact, that they are almost always coincident with small threads or bands of organized lymph, forming adhesions between opposed surfaces of the pericardial membrane. The most common situation of these adhesions is between the great vessels, where they are passing out at the lower and back part of the pericardium, whither the lymph naturally tends both by its own gravity, and by the force of the currents excited by the heart's action, in the fluids around it, to settle and become organized. More rarely, adhesions pass from the surface of the white spots themselves to the opposite surface of the pericardium, or the lining of the sac opposite a spot is puckered, like a superficial cicatrix, so as to render it probable that adhesions had at some distant period existed and been gradually removed.

Regarding the white spots (with which, in all the cases, but two adhesions coincided) as indications of a former attack of pericarditis, it is shewn, by tables appended to the paper, that of 70 cases lately examined by the author at St. Bartholomew's Hospital, 33 had at some time suffered from that disease in a slight or more severe form. More than half of all the males examined, and nearly one-third of the females, had been thus affected.

The subsequent effects of this slight form of pericarditis are not appreciable, nor does it appear to be commonly connected with any other cardiac affection. The particular occasions in which it occurs are uncertain, but it seems to be not an uncommon accident in typhus fever and other acute diseases. Intemperance and its consequences are amongst its most powerful excitants.

## GREAT ENLARGEMENT OF THE PLACENTA.

DR. KENNEDY next exhibited a placenta of extraordinary size. It was a single placenta; and the patient had not had twins. She had a contracted pelvis, and had been delivered by the crotchet at her first confinement; in the second she was delivered without instruments, but the edge of the placenta presented. The placenta occupied more than half the surface of the uterus, and was as large as that in a case of triplets which had been recently in hospital.—*Dublin Journ. of Med. Science.*

# ULCERATION OF THE THROAT

EXTENDING TO THE LINGUAL ARTERY;  
DEATH BY HÆMORRHAGE.

DR. DUNCAN presented the recent parts in this case. The patient, a young man, had been under treatment at the Adelaide Hospital, for ulcerated sore throat, for some time, when he was suddenly attacked with hæmorrhage from the throat, which returned twice in the course of a fortnight. He had left the hospital, but was readmitted, and on the following day the bleeding returned with greater violence, and he was much exhausted. The ulceration was found to have attacked the right lingual artery, which presented a perforation capable of admitting a large sized probe. The os hyoides was found to be carious. Dr. Duncan alluded to cases of the same kind which occurred under the care of the late Dr. McDowell, in one of which the external carotid had been tied with perfect success.—*Dublin Journal of Med. Science.*

## SOFTENING OF THE

# ANTERIOR COLUMN OF THE SPINAL CORD

## IN ITS CERVICAL PORTION.

DR. POWER begged to draw the attention of the society to a well marked and recent specimen of acute softening of the anterior column of the spinal cord. The patient, a woman, aged 50, was suddenly attacked with paralysis of motion in the upper and lower extremities. The bladder and rectum were unaffected; a slight power of motion remained in the limbs. There was no loss of sensation; no fever, headache, or disturbance of intellect. Sensation in the paralyzed portions was perfect. Soon afterwards she was attacked with dyspnœa, and her breathing became diaphragmatic: ultimately the diaphragm became paralyzed, and death took place with great dyspnœa. The spinal column was opened on the following day, and the cervical portion of the medulla spinalis was found softened to a great degree.—*Ibid.*

## RECEIVED FOR REVIEW.

The Eye: a Treatise on the Art of preserving this Organ in a Healthy Condition, and of improving the Sight; to which is prefixed a View of the Anatomy and Physiology of the Eye, with Observations on its Expression, as indicative of the Character and Emotions of the Mind. By J. Ch. August. Franz, Doctor of Medicine and Surgery, &c. &c. Churchill; pp. 296. Gatherings from Grave-Yards, particu-

larly those of London; with a concise History of the Modes of Interment among different Nations, from the earliest Periods, and a detail of the dangerous and fatal Results produced by the unwise and revolting Custom of inhuming the Dead in the midst of the Living. By G. A. Walker, Surgeon. London, 1839.

## APOTHECARIES' HALL.

### LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, Nov. 7.

Thomas Howell, Risborough, Bucks.—William Partridge Mills, Ipswich, Suffolk.—William Anys Rolte, Norwich, Norfolk.—John Brett, Camberwell.—Henry James Browne.—George Wride, Cross Somerset.—Charles Bartholomew Moody, Great Grimsby, Lincolnshire.—John David, Swansea, Glamorganshire.—Jonathan Haigh, Branfoot.

Thursday, Nov. 14.

James Robson, South Shields.—William Braikenridge, Enfield, Middlesex.—Thomas Yate, Madeley, Salop.—William Jeaffreson, Framlingham, Suffolk.—Robert Leadam Sleight, Hull.—Philip Whitcomb, Salop.—Robert Thompson, Mundford, Norfolk.

OF

Medicine and the Collateral Sciences.

FRIDAY, DECEMBER 13, 1839.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF  
SURGERY.

*Delivered at the Westminster Hospital School,*

By BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

SUPPURATION.

**METASTATIC ABSCESS**—*Nature—Symptoms—How produced—Appearances—Treatment.*

**ULCERATION**—*Definition—Distinction—How produced—Nature—Effects—Granulation—Cicatrization—Diagnosis—Curability.*

**PARTICULAR ULCERS**—*Varicose—Cause—Characters—Liability to relapse—Treatment.*

THERE is one variety of abscess so different from those which occupied us in the preceding lecture, that I have thought it advisable to consider it entirely apart—I mean *metastatic abscess*. In that term I comprehend those purulent collections which are suddenly presented in a part of the body, where none of the ordinary signs of inflammatory action exist, whilst at some other and perhaps distant portion of the body suppurative action is present.

*Nature.*—The earliest of those medical men who endeavoured to discover the cause of death, after wounds and great surgical operations, pointed out the existence of internal abscesses in the principal viscera, particularly in the liver and the lungs. Later observers having observed their frequency and their gravity, did not hesitate to regard them as the most frequent cause of death in wounded persons. This fact being established and converted into a law, namely, the simultaneous existence of suppurating surfaces and numerous visceral abscesses, gave birth to many theories.

Many wounds and operations being performed in persons in strong health, it was difficult to conceive that the visceral case discovered after death had preceded the wound; yet, as it is certain that a great number of organic diseases are long latent, and as these abscesses, from their number, their seat, and from other circumstances, were supposed to have an analogy with suppurating tubercles, many persons have maintained that these abscesses were the result of the development of pre-existing tubercles. Though this theory may not be entitled to universal adoption, it does not merit absolute exclusion, because I apprehend there are cases of scrofulous disease for which recourse has been had to amputation, where visceral abscess has occurred, and has been a consequence of the breaking down of pre-existing tubercles. Certain it is, however, that these abscesses are developed in the healthiest and strongest individuals, the most formidable symptoms succeeding suddenly to a condition apparently the most satisfactory.

*Mode of production.*—The idea of *metastasis* rested upon the following reasons:—“The diminution or suppression of external suppuration, which is the constant prelude to the formation of internal abscess; the absolute identity of the pus of the wound and that of the abscess; the absence of those general and local symptoms which are said to be characteristic of visceral inflammation; the rapidity with which these abscesses are formed; the absence of inflammation around them; the presence of pus in the veins and in the right cavities of the heart, in the midst of coagula.” Supposing this doctrine to be admitted, the agent by which pus is transported from the wound to the viscera is supposed to be the veins, which exercise an absorbing power. Some persons are disposed to think that the lymphatics are the agents; others, that both are con-

cerned in producing the effect. The opponents of the humoral pathology objected to the one and the other, and maintained that they were developed by *sympathy*. If, say Desault and Bichat, the liver be so frequently affected in wounds of the head, it is because the liver and the gastric organs are connected by very intimate sympathy with the brain. Others have maintained the opinion that these abscesses are owing to a simultaneous contusion of the head and the liver: in a few cases this may be true, but the abscesses we are considering may not only affect the viscera, but the synovial and the serous, the cellular and muscular tissues, and are independent of all contusion or concussion.

Surgeons of the last century paid much attention to these abscesses occurring in the liver after wounds of the head; they believed this organ to be their exclusive seat: it is true in this organ they are more readily observed, from the difference in colour; it is true, also, I believe, that they more frequently excite inflammation in the serous covering of the liver than in that of the lung, but still they are oftenest presented in the lung. In the spleen they are less frequent, and are darker in colour and less well circumscribed. In the brain we sometimes see an appearance as if the surface were studded with pus, and the smell is very offensive. In the heart the quantity at a point rarely exceeds a drop. But where these collections are most remarkable is within and around joints; they seem to prefer the larger—the knee, the hip, the shoulder, the elbow; they rarely affect a single joint, usually affecting several at the same time. In an extremely short time they effect the complete disorganization of the tissues of the joints. These collections are most frequent after parturition, great operations, and small-pox.

*Symptoms.*—The salient points of such abscesses are the astonishing rapidity of their production—their occurrence frequently without pain, heat, or redness, at the part, so that we are unaware of their existence until they point. Petit, in speaking of them, says these deposits are formed in a very short time, and before any indication of suppuration is presented, in consequence, probably, of the pus being already formed in the blood. This absence of pain, and of the ordinary symptoms of inflammation, is their character, whether superficial or deep-seated. Whatever internal organ is affected, the signs are very illusory; the only tolerably constant phenomenon attending them is the rapid and inexplicable supervention of serious symptoms, particularly of rigors, in the course of a suppurating wound. Externally we have certain signs to guide

us; there is swelling, there is acute pain, instantaneously developed.

*How produced.*—How are these abscesses occasioned? In consequence of their development during the progress of suppuration, at a distance from the suppurating point, and without apparent inflammatory action, it has been conceived that pus was absorbed from the suppurating surface, carried along by the venous or lymphatic vessels, and deposited elsewhere; and this appeared the more probable, because the suppurating surface was dried up; but then these abscesses sometimes happen without suppurating surfaces, and the quantity of pus deposited in different organs is out of all proportion to the frequently small surface from which it has been supposed to proceed. In the greater number of cases, by careful examination we shall discover venous inflammation; this inflammation is suppurative; pus is mixed with the blood, and is carried into the circulation; the blood is changed, and excites the capillary structures so as to produce abscess. This seems to me to be the most reasonable explanation of these abscesses. They seem, therefore, to depend upon a purulent condition of the blood, which is produced by venous inflammation; but I by no means deny that other causes may not bring about a purulent condition of the blood; the inoculation of the pus of small-pox seems to be capable of producing such a condition.

There are three obvious modes by which pus may be introduced into the circulation; direct injection into veins or arteries; attraction exercised by an open capillary vein; and phlebitis. The *direct injection* of pus into veins produces the most serious consequences, similar to those which may succeed to wounds and great operations. Marcchal, adopting the experiments of Barry, maintained that a powerful attraction is exercised by veins upon the fluids in connection with their open mouths. But phlebitis is no doubt the common source of all the accidents which supervene as a consequence of wounds of veins.

These abscesses or purulent collections succeed, it is true, to amputation, to fractures, to great wounds and great operations, and to parturition. But this condition may be developed in the absence of great wounds and great operations; it may succeed to injuries of comparatively small veins; indeed, any injury which may induce venous inflammation may occasion this state. After amputation the disease is rarely developed before the tenth day, but it may succeed earlier; I have known the disease to occur on the fourth day after bleeding. Their common seat is the thoracic and abdominal vis-

cera, and they seem to manifest the strongest predilection for those best supplied with blood-vessels—lungs, liver, spleen, brain, heart, and very rarely the kidneys; it may occur in the cellular tissue around veins, or even in muscular structure. Following a law of predilection for the most vascular parts, they are presented at the base of the lungs, the convexity of the liver, and they are commonly seen at or near the surface of organs, and not unfrequently excite inflammation in their serous covering. They rarely attain great size, but are often extremely numerous, studding the entire substance of an organ. The part of the organ in which these collections are found at first sight appears in nowise changed; and this has given cohesion to the idea that the matter is deposited in the part by the blood vessels, and is not the result of inflammatory action at the spot. Hunter, and others who have succeeded him, observed “many small vessels converging to the point, and containing purulent matter.” I believe that at first they are true depositions, but they excite inflammation at the part; the circle of tissue which is infiltrated seems to break down, and an ordinary abscess is thus formed.

A short time since I examined the body of a woman who died from purulent peritonitis. Many of these abscesses were found in the liver, in various stages of development. At first they presented a very dark ecchymosis, the dark point becoming harder, rounder, and blackish: pus gradually infiltrates this point, and converts it into a true abscess, which softens from the centre to the circumference. At first the surrounding tissue looks healthy. If now we reflect that these abscesses supervene in the course of a phlebitis; that in a few days purulent infiltration occurs, and is soon succeeded by abscess; that they present special characters, such as are not seen in ordinary inflammation of a healthy tissue; that close to the altered tissue we usually find healthy structure; that the same condition may be observed after external and internal phlebitis; that those grave symptoms which accompany these abscesses strongly resemble those which indicate a miasmatic infection of the fluids, we must admit that if the transport and admixture of pus with the blood, in the course of a phlebitis, are not materially demonstrated, the opinion is at all events extremely probable; and I think the experiments of Cruveilhier (*Dict. de Méd. et Chir. Pratiques*, *Phlébite*) render the probability almost a certainty, and demonstrate that pus circulating with the blood is arrested in different parts of the capillary circula-

tion; that where so arrested, it more or less rapidly determines capillary phlebitis, or circumscribed inflammation, which quickly passes through its periods to produce abscess; that this pus is most frequently arrested in the lungs; next in frequency, in the liver; then in the spleen.

Reasons are not wanting to prove that the lungs are for foreign substances introduced into the general circulation, and the liver for those introduced into the abdominal venous system, an inevitable recipient, and in many cases an impassable barrier. So that the phrase of the ancients, *vena portarum, porta malorum*, is an exact and precise expression of a practical truth of the highest importance.

*Treatment.*—The treatment of this disease, so far as I know, is powerless to change the condition of the blood; it might be possible to arrest the local phlebitis, and to prevent the introduction of pus into the blood. This must be done by pressure by means of bandaging along the limb, to seek to obliterate those veins, and by local blood-letting. With these I have been accustomed to exhibit salines, with acid, largely, together with camphor in large doses, quinine, and the most energetic stimuli. I have not ventured to push mercury and emetics, which some have recommended, because the signs of prostration were so pressing, and because I have seen them fail in other hands. Some persons strongly advocate the use of purgatives, because the injection of pus into the veins of animals is followed by abundant and very fetid stools when they recover. It is, then, evident that the treatment of this affection must be concentrated at the first period, for when suppuration is once declared, and pus gets into the circulation, medicine is at present powerless. Frequently we are enabled to arrest phlebitis succeeding to blood letting by the plentiful application of leeches in the course of inflamed veins: in fact, we are often enabled to arrest it, wherever seated; but pass that period, and let general symptoms be manifested, and general and local bleeding will be without effect, for although with the blood we may remove a portion of the evil, it is unfortunately constantly renewed.

#### ULCERATION.

*Definitions.*—I have carefully looked over a great number of definitions of ulceration, and have found none to which serious objections do not attach: for instance, if we take those of Petit and Boyer, the former defines an ulcer to be “a solution of continuity, from which pus, puriform, sanious, or other matter, flows.” Now a wound is a solution of continuity from which pus flows. The latter says, “an ulcer is a

solution of continuity of the soft parts, more or less ancient, accompanied by a discharge of purulent matter, and kept up by some local mischief or some internal cause." Here, again, there is nothing to distinguish an ulcer from a granulating wound. Mr. S. Cooper says, "ulceration is the process by which sores or ulcers are produced in animal bodies." Very true; but it does not state what an ulcer is. The distinction which I prefer is that of Richeand: he says, "there is between a wound and an ulcer this characteristic and notable difference; that the first, produced by an external cause, essentially tends towards a cure, arriving at that state by a natural succession of periods, unless any thing should arise to derange its course. It is an acute disease, tending to a fortunate solution." An ulcer, on the contrary, is a chronic affection, produced or maintained by an internal cause: the solution of continuity is not here the principal disease; it is only a symptom of local or general internal affection. To this internal affection the ulceration is owing, and it prevents its cicatrization."

*Distinction between wounds and ulcers.*—Certain particular distinctions may be made between a wound and an ulcer. A wound results from the action of a foreign body; the cause of an ulcer is, on the contrary, inherent in the economy; consisting either in a particular disorder of the solids or fluids, or in a morbid condition of the part where the ulcer is situated. A wound is therefore an idiopathic affection; an ulcer is always symptomatic. A wound essentially tends to a cure, the action of its cause is instantaneous; an ulcer tends to enlarge, because its cause is still subsisting. The treatment of a wound is mechanical—surgical; that of an ulcer is medical—topical means are of less importance.

Any means physical or vital—a wound, an abscess, gangrene, or inflammatory action, by which a solution of the continuity of our tissues can be produced, may be an immediate cause of ulceration, because in the one case and in the other nature seems for a time powerless to repair the injury in the ordinary way. It is therefore very necessary to distinguish between the agent by which a wound is inflicted, and that by which the ulcerative action is kept up. Supposing a physical injury to be attended by a solution of continuity, the system being impregnated with syphilis, it is said that the wound may assume the character of a syphilitic ulcer. Delpech describes a case where the loss of continuity succeeding to the removal from the forehead of a flap for the purpose of repairing a deformity of the nose, assumed all the characters of

syphilitic ulceration; the patient at the time suffering from that disease. A wound in a scrofulous person may be characteristic of scrofula; the same may happen in a person suffering from scorbutus. We must therefore understand an ulcer to be, a loss of substance of some part of the body, which, from some peculiarity, local or general, of the constitution, manifests no tendency to heal, so long as that particular condition exists. Farther than this I am unable to go: I cannot say why a scrofulous ulcer ordinarily manifests so little tendency to heal; those probably are secrets of nature, which may never be revealed to us. We must therefore be content to take these as facts which, in the present state of our knowledge, are inexplicable.

*How produced.*—That great light of our profession, John Hunter, conceived that an ulcer was the work of an absorbent action. "This process," says he, "of removing whole parts in consequence of disease, in some cases produces effects which are not similar to one another; one of these is a sore or an ulcer, and I therefore call it ulcerative." "This operation of the absorption of whole parts, like many other processes in the animal economy arising from disease, would often appear to be doing mischief, by destroying parts which are of service, and where no visible good appears to arise from it; for it is this process which forms a sore, called an ulcer."

I confess my inability to understand that all ulceration is produced by an absorbent action: for instance, if I insert a small quantity of the pus of a chancre under the integument, I excite inflammation; that action is accompanied by exhalation, not absorption; serous fluid is exuded under the integument, the cuticle is separated, gives way, the entis is exposed, and no attempt is soon made to cover it. In this way an ulcer is formed: whether the extension of a surface so formed be owing to absorption removing the tissues at the part, or to suppurative action breaking down the implicated tissues, seems to me a matter not so well determined as it is the custom to believe. Of course I mean ill-conditioned suppurative action, in which no disposition to reparation is shewn. Many ulcers commence by a tumefaction of the part with induration; they are more or less indolent, more or less chronic. From this state of induration it passes to a state of softening, in which the tissues acquire a pulsatous character; the integument gives way, and they are discharged. Tuberculous matter or pus again deposited in our tissues, become at the end of a certain time a cause of ulceration. These products have a re-

markable tendency to make a way of escape for themselves, and they frequently induce ulceration. Gangrene is a common cause of ulcers, and the manner in which it produces them it is easy to conceive. The affected part, deprived of life, is a true foreign substance to the living tissues; irritates, inflames them; pus may be formed; the eschar or slough is raised and thrown off; a solution of continuity or ulcer is produced, which may be long in healing.

*Nature.*—However ulceration is produced, left to itself its course is to extend; but the rapidity of its extension seems to vary with the nature of the ulcer: though involving all the surrounding tissues, all do not give themselves up to this destructive action with the same facility: aponeurosis, tendon, cartilage, and bone, resist for some time, and ultimately mortify, because the neighbouring tissues are broken down, and they cease to possess the necessary means of nutrition. Sometimes the progress of ulceration is very rapid, destroying in a short time a great extent of parts; sparing no tissue, not even blood-vessels, and thus occasionally causing hæmorrhage. In other cases, after having commenced by making rapid progress, it may remain for a considerable time stationary, or even may end suddenly by cicatrization.

*Effects.*—The effects of ulceration vary with the extent, with the importance of the part affected, with its duration, and with the constitution of the patient. An ulcer may destroy a great extent of integument, of subcutaneous cellular tissue, or muscular structures, from which great difficulties are experienced in inducing cicatrization, and the patient is enfeebled by pain and purulent secretion: the latter, when considerable, greatly exhausts the vital powers. The extent of destruction produced by ulceration, the disorders which it may set up in the constitution, may be so great, as to render it necessary at any cost to remove such a dangerous influence; may make it imperative to recur to amputation. By destroying the muscles of a limb, ulceration may destroy the functions to which the organ is destined; by destroying blood-vessels it may produce hæmorrhage: again, there are organs whose texture is very delicate, or whose conformation is very important, which cannot undergo ulceration without damage or destruction: the transparent cornea is in this situation; ulceration often attacks it, sometimes perforates it, causing occasionally the utter extinction of the functions of the eye.

*Tendency.*—When, by medical or other means, this state of the constitution is changed, the ulcer, even in the absence of

any local treatment, may manifest a disposition to heal: healthy granulations are developed, healthy pus is secreted, a cellulo-fibrous tissue is formed, it gradually extends, usually from the circumference to the centre of the ulcer. When it covers the surface, the cicatrization is complete.

*Granulation.*—We must now shortly consider granulation, without which all ulcers and all wounds, not healed by “first intention,” cannot heal. In 1823, Pauli published a work in which he very elaborately examined almost all the explanations of this phenomenon which had been propagated up to that period; and to this work (*Memoire Physiologique Chirurgicale sur la Guérison des Plaies*) I beg to refer all who are curious on this subject. Hunter, Home, and Thomson, in our own country, have laboured, and with considerable success, to elucidate the subject.

You are all familiar with those inequalities termed granulations which may be observed upon the surfaces of ulcers or of wounds healing “by second intention.” They vary much in size and in colour. Gueterbock has observed them largest where the loss of substance is greatest, smallest where most superficial. My own experience does not enable me to confirm this observation; I have not succeeded in making out that this principle is general in its application. When healthy, their colour is of a more or less vivid red, but in this there is also much variety. Thomson observed that their temperature was two or three degrees above the natural temperature of the body, and this observation is confirmed by Pauli: in this experiment I have not been so fortunate as to be able to confirm the observation. When the granulations are covered by a poultice, I have found as great a difference as is stated between them and uncovered parts; but between the granular surface and the surface little removed from the margin of the ulcer, and also covered by poultice, the difference was very small, though, as far as it went, it confirmed their observations. Their tissue, though soft, is not wholly unresisting, but it bleeds upon very slight violence. Gueterbock has removed a very thin slice of a granulated surface, and placed it under a microscope. At the edges he saw irregular globules of pus, some globules of blood, and some bodies of a special character, very similar to those which Henlé termed mucous cylinders. In the interstices between those bodies, he observed very delicate transparent filaments, the globules being, as it were, between the filaments. These filaments were composed of fasciculi of very attenuated fibres. The corpuscles of these fibres presented a diameter about half that of the globules of the blood, but these

filaments always extended from one side to the other. He made an experiment to determine whether these granulations contained gluten. Those taken from a horse, well washed and boiled for seven hours in distilled water, gave no indication of gluten. The water obtained from it was precipitated by acetic acid and a solution of alum, but the two precipitates were insoluble in an excess of the re-agents employed; he therefore concluded that pyine was the substance which the granulations contained. He thinks that the filaments of granulations are formed of fibrin, like those which are observed in coagulated fibrin of the blood. He thinks that the globules found between these filaments are similar to globules of pus. As to the newly-formed vessels in this regenerated substance, he has never seen them take any constant direction. Sometimes, after plunging into alcohol a lamina of this matter, for the purpose of coagulating the blood in those vessels, he has observed one principal canal describing a semicircle, and dividing into smaller ramifications, which open upon a second, larger, and straighter canal; one, perhaps, being an artery, another a vein. Sometimes the blood has seemed extravasated and extra vascular. In fact, he has seen so many different arrangements of vessels as to induce him to believe that granulations are not, as was believed by Pauli, unequally formed of a capillary net-work. The surface of the mass is, however, better supplied with vessels than the deeper seated parts: this is easily seen by making a perpendicular section; the surface is most injected, the deeper seated part paler.

In all suppurating wounds or ulcers this new substance is formed. The doctrine of Fabre, Louis, and others, which maintains that such solutions of continuity are cured by a drawing in of the edges, and denies all regeneration, is, I believe, utterly incorrect. Equally incorrect, I apprehend, is the doctrine of intussusception, or a development from within outwards from the fundus and lips of the ulcer.

Pus is necessary to the production of granulations, from whence we may conclude that this matter has a more important place than a simple excretion, since it is found in the granular tissue. Suppuration, then, seems to be anterior to the production of granulations. Hunter appears to have been deceived when he thought he had seen granulations without suppuration. It is certainly necessary to reject the opinion of Bichat and others, that suppuration is preceded by granulations, or those of Gruithuisen and Pauli,

who thought that both appeared at the same time.

Granulations unquestionably present newly formed vessels; the opinion of Hune, that they did not exist in this regenerating tissue, is manifestly untenable. Whether or not there be nervous filaments it is difficult to determine; the sensibility of the new tissue would certainly lead me to suppose that they were well provided with nervous energy. How this tissue is formed, and how it passes to the state of a cicatrix, we cannot determine.

*Diagnosis.*—To diagnose an ulcer is not difficult, but to determine to what particular cause it is owing is a much more serious matter. There may be local circumstances to facilitate this; thus, take a syphilitic ulcer, usually they are of unequal surface, their edges may be as if perpendicularly cut, and they are surrounded by a brownish areola; but frequently these characters are not presented or are ill expressed, and, therefore, to ascertain the cause will often be a matter of difficulty.

*Cicatrization.*—It must, therefore, be evident to you that an important condition in the cure of ulcers is the destruction of the cause. It is true nature will sometimes cure an ulcer without satisfying this condition, but the cicatrix is rarely solid, and the ulcer will often, after a short time, break out again. When by methodical means we have destroyed the condition upon which the ulcer depends, it will gradually assume the characters of a simple wound in process of cure; the surrounding tumefaction is dissipated, the edges become thinner and less raised, the ulcerated surface presents healthy granulations, it is covered by healthy pus, the edges become paler and drier, and covered by a white pellicle, a certain sign of cicatrization which proceeds from the circumference towards the centre. The fibro-cellular tissue, developed upon the surface of a suppurating wound to constitute the cicatrix, has a very decided retractile tendency, by which a comparatively large ulceration may, when cicatrization is complete, be brought into very narrow limits. At first cicatrization proceeds rapidly, especially where parts are not resistant; afterwards, the progress under even favourable circumstances, is less marked. A circular ulcer is slower in healing than an oblong or an oval one. The ulcerated surface during this process presents granulations, which become so much redder, more distinct, and more projecting, as the process is more decided. Where the ulcer has been extensive, it happens that when the surface has undergone a certain reduction the process often seems suspended, the edges become red or violet, the surface acquires a tint

darker than the vermillion it before presented, the granulations flatten or disappear, the suppuration becomes thinner, less elaborated, and things may remain in this state for a long time; this is particularly the case with serofulous ulcers, in winter. The stationary condition of an ulcer whose cause is destroyed sometimes depends upon different circumstances; irritating applications upon the surface itself, any exercise which exposes the surface to friction, debility, gastric disease, or any other general affection, capable of exercising a sympathetic influence upon the skin, may have a similar result. If the cause of ulceration have been destroyed, and yet, after cicatrization has proceeded to a certain extent, it becomes stationary, in spite of ordinary applications, and it is observed that the long continuance of morbid action in an ulcerated surface, sometimes unfits it for cicatrization, we may frequently succeed by the use of caustic in destroying the old surface. When the eschar comes away the cure may often be rapidly accomplished.

Many circumstances favour or oppose the cicatrization of ulcers; those developed in parts where the skin is loosely adherent to subjacent parts, often heal very rapidly; those which affect parts very adherent to subjacent parts, and in a continual state of tension, are often very refractory; those on the internal surface of the leg, and those seated about the ankles, are in this case. Again, the state of the atmosphere is not without its influence; during damp cold weather an ulcer will often yield thin and sanious pus; any change in the organization they rapidly feel, their surface becomes pale or grey, or fungous, the suppuration is diminished, is grey or serous; position, again, will produce many changes; the erect position will often cause an ulcer of the leg to bleed.

*Curability.*—As to their curability, those of the lower limbs are more obstinate than those of other parts of the body; those developed near points where bones project are often tedious; those which are circular do not cicatrize as soon as those of any other form; those which are old and callous are not so easily healed as those which are recent, and whose edges are exempt from induration.

In this lecture we propose to consider only a particular class of ulcers affecting the lower extremities, and usually more or less dependent on varicose veins. Specific ulcers, such as serofulous, scorbutic, syphilitic, and cancerous, will be considered with the several diseases to which they belong.

*Particular ulcers—Varicose.*—Under the term *atonic ulcer* it is customary to range all those which seem to be a consequence

of local or general debility; their more common seat is the legs, parts farthest removed from the centre of the circulation. Of the two legs, the left is much more frequently ulcerated than the right; in the proportion, in my experience, of 93 to 27. This is not very dissimilar to the experience of Ponteau, and is manifestly opposite to what we might *à priori* expect, because the right leg is usually the first advanced, and, therefore, more exposed to accident than the left.

*Causes.*—Ponteau conceived that the reason of this was an interference with the venous circulation, by the pressure made upon the left iliac veins, by the distended sigmoid flexure of the colon. There may be truth in this, but I know of no direct proof of the fact, if fact it be. There is a certain kind of confirmation of this view of the subject, afforded by the frequent existence of a varicose condition of the veins of the legs; of 203 cases of ulcered leg occurring in the left side, 159 were manifestly connected with this condition of the veins. Some persons incline to the opinion that it is dependent upon another circumstance, the greater feebleness of the left than the right side. Whatever may be the predisposing cause, certain occupations seem to excite their development; especially those which require the person to be much of the day in the erect position—printers, washerwomen, are much exposed to it. Such ulcers are extremely common among the rice-workers of Piedmont.

At the same time, therefore, that I believe the exciting cause of by far the larger number of cases of ulcered legs to be the vertical position of the body long maintained, yet that position does not account for the greater frequency of the disease on the left leg than the right, neither does it explain why varicocele is so much more frequent on the same side; there must be some other cause for this circumstance; whether it be an original weakness, or whether it be such an obstacle to the return of venous blood as I have already alluded to, I cannot tell. The erect position which certain occupations require during the greater part of the day, tends to retard the backward progress of the blood, its course has the influence of gravitation opposed to it, certain of the valves give way, the weight of the column upon others increases, they yield in turn, the venous parietes yield, the distension increases, the veins are dilated, become tortuous, varicose, blood finds increasing difficulties in its reflux course, and a constant state of congestion of the limb is the consequence. Certain observations, recorded by Bouillaud, many years ago, in the Archives, very clearly shew that one

effect of mechanical obstacles to the passage of blood in veins is an exhalation of serous fluid through the parietes; this fluid, but more or less coagulable, matter, distends, and often breaks down the cells of the cellular tissue, and produces a spongy ill-conditioned state of that structure; the cutaneous integument over it is not well nutritified, it becomes thin, brownish or reddish, and ready to give way from very slight causes, and the ulcers which succeed are often, as might be expected, painful and obstinate; most commonly the ulcer is callous or indolent, but it may be irritable; it may have raised edges, or they may scarcely be presented above the ulcerated surface. In the progress of age, even when large branches of varicose veins are not presented, yet the veins are less active, and if the erect position be maintained for several hours every day, the cellular tissue will undergo changes, the same in kind, though less in degree, than those to which I have already alluded; this is the reason why a wound on an old man's leg is long in healing, why a similar wound upon a younger person, whose tissues are comparatively healthy, heals readily. Of ninety-seven cases of ulcerated leg admitted last year, sixty-seven were women; it may be asked why this difference? It is because forty-nine of those women were either washerwomen, laundrywomen, or wretched creatures living on the charity of the public, obtained by walking the streets during the greater part of the day, and because the causes of venous obstruction are more direct in women than in men. The gravid uterus, in most women, gives sufficient evidence of this; the cedematous condition to which I have alluded is the ordinary condition of the legs in an advanced period of pregnancy, but much of it is dissipated with the removal of the cause.

Sir E. Home was wrong in his statement that all varicose ulcers are developed more or less immediately in the course of the veins; he does not seem to have been aware that the infiltration was general, and that they might appear on any part: he confines them to the inside of the leg, just above the ankle. Taking sixty-seven cases of varicose ulcer, I found twenty-nine on the outside. The fact is, one saphena is affected almost as frequently as the other, and we might therefore expect that the outside of the leg would suffer almost as frequently as the inner.

*Characters*—Although a varicose ulcer, when dependent upon no other cause than the diseased vein, does usually put on a particular appearance, there is nothing uniform about this. Take four cases of ulcerated leg, in each the cellular tissues are greatly infiltrated, the leg is half as large

again as natural, the veins are varicosed, though somewhat concealed in the infiltrated tissue; you will have four ulcers essentially different. To say, therefore, that a varicose ulcer is seldom very deep, that when it spreads it is along the surface, that it is usually oval, the ends of the oval pointing vertically, that the edges of the surrounding skin are commonly neither thick nor irregular, but are imperceptibly lost in the ulcer, that the pain which it gives is seldom from the surface, for pressure does not increase it, is to describe a case which you may often realize, but which has no direct or uniform relation with varicose veins: of twenty cases of ulcerated leg occurring during the last three months in varicose subjects, in only one was that condition realised, and in that case, a woman of fifty-five, the veins were varicosed only to an inconsiderable extent.

*Liability to relapse—Treatment*.—Varicosed ulcers are very susceptible, and especially liable to relapse—the horizontal position, and equable compression, will in the great proportion of cases effect a speedy cicatrization, but no sooner are these means dispensed with, than the original causes of disease are again in action to reproduce the ulcer. Although the horizontal position by facilitating the return of blood, facilitates cicatrization, yet equable compression firmly made by carefully bandaging the limb, will afford the veins the support they require, and will accelerate the cure. But the dilated veins will not, either by bandaging or position, resume their healthy condition, and, therefore, the cure is only temporary. The patient must employ the bandage, or the laced stocking, to prevent the recurrence of ulceration. There are many persons whose condition in life does not admit of their using these means, and they are annually the denizens of a hospital, or attendants upon a dispensary. It is by giving this support that the strapping system of Baynton and others procures the rapid cicatrization of these ulcers; but, although the cure is rapid, the relapse is also rapid. Baynton was accustomed to apply the straps completely around the limbs, commencing an inch below and extending to an inch above the ulcer, and now and then they were found to act like ligatures: at present, when this means is employed, the strap only partially surrounds the limb; for instance, if only the internal saphena be affected, the strap need not cover the external, and *vice versa*. Even then, it will often irritate the skin, and if bandages were properly applied these straps would be quite unnecessary.

Attempts have been made to effect a permanent cure by employing some means of obliterating these diseased veins. A small

knife has been passed under the skin and a section made; the hæmorrhage is trifling and soon suppressed by slight compression. Caustics—caustic potash and soft soap, of each equal parts—as well as other formulæ, have been applied upon the integuments in the course of a vein, so as to make an eschar deep enough to implicate the vein; the ligature has been used for the same purpose, but although the immediate object, that of obliterating a vein, may be attained by either means, the cases of fatal inflammation of veins produced by them have occurred with sufficient frequency to induce the general abandonment of a mode of treatment which is not unlikely to substitute a fatal disease for a bearable infirmity. Within the last three or four years a new mode of obliterating these veins has been a good deal employed. I have frequently used it myself, and with the exception of a case which occurred to Mr. S. Cooper, and another to Velpeau, I know of no bad consequences which have followed its employment. A hare-lip needle or two are passed under the largest varicose vein, a little removed from the ulcer; around each a thread is twisted, not very tightly, but sufficiently so to prevent the passage of blood, but not to injure the integuments, and in five or six days the obliteration is complete. It may be asked, whether when the internal saphena is obliterated, the blood, in finding its way back, does not dilate the smaller veins, and induce in them a varicose state? This is not usually the case; much of the blood seems to get back through the deeper seated veins, which are better supported, and, therefore, less disposed to give way. It is probable, if care were taken to ascertain the condition of the patient's general health, that fewer fatal cases of phlebitis would occur. As to the use of internal medicines in the treatment of these ulcers, any thing beyond a careful regulation of the bowels will be unnecessary. I do not, however, wish to convey an idea that all ulcers of the legs will readily yield even to any treatment; if very irritable, leeches are sometimes necessary; sometimes opium has a good effect; if very sluggish, caustic may be necessary; if the edges are much raised, careful compression will be required; but these are exceptional cases; the horizontal position and bandaging will certainly cure nineteen-twentieths of the cases which are presented.

I am quite alive to the occasional inconveniences of confining patients for weeks to bed for the purpose of giving them the advantage of the horizontal position, as well as compression; and it therefore may be a question whether in many cases it may not be as well to rely on careful bandaging alone, and allow them to pro-

ceed about their ordinary avocations. Certain it is that the ulcers do not heal so quickly under this system: neither do I believe, as some persons do, that the cure is more permanent; it has, however, this advantage, that occasionally persons from habit continue the bandage, and thus lessen the chances of relapse. Under the bandage any irritating application may be made. You should accustom yourself, whenever opportunity offers, in applying bandages, few students are sufficiently impressed with its importance. A bandage should always be so well applied that although the patient walk about, it should not be deranged for several days. The bandage should be made of flannel or calico, the latter often irritating, but it has the advantage of greater elasticity. The breadth of the bandage should not be more than two inches, otherwise it cannot be put on smoothly; the length must vary with the size of the limb; it need not extend beyond the roots of the toes, nor usually beyond the small part above the calf. The best means of acquiring tact in the application of bandages is frequent practice—and this you can have no difficulty in obtaining.

When of moderate extent ulcers may subsist long without inconvenience; but those which implicate large surfaces insensibly establish in the system a new habit, which becomes ultimately as it were a physiological condition. It is particularly in feeble and irritable subjects, those who have some visceral derangement, and in aged persons, that this new habit becomes of great importance. Thus the debility produced by an old and extensive ulcer may become dangerous, and yet the local affection having existed so long, and the state of the constitution being so deteriorated, we hesitate to suppress the action existing at the part. It is believed by many persons that worse dangers are often developed by such suppression; thus Delpech states, that he has seen hydrothorax and anasarca succeed to the sudden cessation of old suppuration. Fabricius Hildanus, Heister, Sharp, Ledran, and others, mention cases of apoplexy, diseases of the thoracic and abdominal viscera, succeeding immediately to the cure of certain ulcers. Camper and Bell maintain an opposite doctrine. My own experience would induce me to coincide with the former opinion, though I have not yet collected a sufficient number of cases to make the matter clear. It is possible that careful diet, purgatives, and the establishment of an issue, might avert the occurrence of such diseases as have been referred to.

LECTURES  
ON  
THE PHYSIOLOGY OF THE  
STOMACH,

*Being the Gulstonian Lectures for 1839;  
delivered at the Royal College of  
Physicians in London,*

By R. B. TODD, M.D. F.R.S.

Fellow and Censor of the College; and Professor  
of Physiology, and of General and Morbid  
Anatomy, in King's College, London.

LECTURE III.

*On the structure of the mucous membrane of  
the stomach.*

It is from an accurate knowledge of the minute structure of the mucous membrane of the stomach that the most correct deductions may be made, in a physiological point of view. Nor, indeed, is this knowledge less important and valuable to the pathological inquirer, whose aim should always be to detect the seeds of disease before they have yet begun to germinate. But it can scarcely be expected that any degree of success shall attend researches into the morbid changes of any structure, if the observer be ignorant of its anatomical characters in health. I feel that I cannot too strongly urge upon pathologists generally the necessity of obtaining a more intimate knowledge of the natural structure of organs, than that commonly possessed, in order to investigate with success the alterations to which those organs are liable. On no one subject are the statements of morbid anatomists less to be relied on than with reference to the morbid changes of the mucous membrane of the stomach; nor is there any matter on which more crude and inconsistent reports have been published. It is but a few years since the variations in the supposed morbid states of the liver were pointed out, by the relative proportions which the so-called red and yellow substances of that organ bore to each other; but now that we are acquainted with the minute anatomy of this viscus, we are able to estimate correctly the degree of value which may be assigned to these varieties of colour; we know, indeed, that these varieties of substance in the liver, although for many years described by anatomists of great and deserved reputation, were, in fact, no more than fictions, adopted for the purpose of explaining that which they felt it difficult to explain, only because they were ignorant of the real anatomy of the organ.

Notwithstanding the attention which was given to the investigation of the anatomy of the tissues, in France and Germany especially, and in a less degree in this country, but little advance had been

made in our knowledge of that of the gastric mucous membrane, and although in the writings of Haller, Hewson, Cuvier, Meckel, and Home, we can trace some approach to a knowledge of the true structure of this membrane, one is surprised that, with the means and opportunities, and the zeal, which those anatomists possessed, they did not come nearer the truth. Recent microscopical investigations have, however, completely revealed to us the minute anatomy of this membrane; those of Dr. Spratt Boyd were published in the Edinburgh Medical and Surgical Journal, for the year 1836, and constitute a very valuable, extensive, and, upon the whole, accurate series of researches. Shortly afterwards the indefatigable Purkinje investigated the subject, but I have only seen a passing allusion to his examination, in a paper by himself and Pappenheim, on the influence of electricity upon artificial digestion, in Muller's Archiv. for 1838; and at the end of last year a paper appeared in the same journal, from the pen of Professor Bischoff, of Heidelberg, containing a very full account of his examination of this membrane. Before I had the advantage of perusing this paper, I had myself examined the membrane of the stomach in several animals of each of the vertebrated classes, and had obtained a knowledge of its intimate texture, which, in the main points, agrees with the descriptions of the authors to whom I have just referred. The account which I shall give in the present lecture is derived altogether from my own observations.

To obtain a perfectly satisfactory view of the anatomical characters of the gastric mucous membrane, it is necessary that the stomach of an animal quite recently dead, should be selected for examination. The surface of the membrane is constantly overlaid by a more or less thick layer of mucus, generally tenacious, and adherent to the subjacent cells, from the mouths of which it is poured out. There can scarcely be a doubt that this mucus exerts a destructive influence upon the membrane with which it is in contact, and if it be allowed to remain in contact for a sufficient length of time, the surface becomes so softened and, as it were corroded, that all traces of the natural structure of the tissue completely disappear. Hence the first care of the anatomist, after having obtained a sufficiently recent stomach, must be to remove completely the adherent layer of mucus. Nor must this be done by any violent mechanical means, such as scraping the surface with a knife, or the edge of any sharp instrument; it may be completely and satisfactorily accomplished by directing a stream of water upon the surface: let the whole mucous membrane be

well washed under a large stream flowing from a cock, and then with a good syringe direct a moderate stream upon each portion of the membrane in succession; by these means in a short time the layer of mucus may be very completely removed, and then the stomach may be kept in a weak spirit for an indefinite period, without suffering any alteration in its structure. I have in this way preserved for many months several injected and non-injected specimens, which completely retain their natural appearance, and will, I have no doubt, continue in the same condition.

Thus prepared, the structure of the membrane may be ascertained by various modes of examination. A portion of it injected or otherwise, pinned on a piece of cork, and illuminated by light thrown upon it by a condenser, may be examined under water by the simple or compound microscope, and with the aid of a lens, or object glass, of even very low magnifying power. I find that the Coddington lens, or in the compound microscope an object glass of two inches focal distance, affords a most satisfactory view of the surface, arranged as I have stated. In a successful injection the mode of distribution of the capillaries is beautifully seen, but they are so numerous as to conceal the arrangement of the membrane, and, therefore, the anatomist must not confine himself to the examination of injected specimens only. Thin vertical sections of the membrane must next be made, and if these be sufficiently thin they may be examined as transparent objects; but the structure is very well seen when they are placed on a black ground, and examined as opaque objects. I have found it also extremely useful to make very thin horizontal sections at various depths of the membrane, and to examine them by transmitted light. This mode of examination, which has not, so far as I know, been adopted by other observers, has enabled me to satisfy myself about several points in the structure which without it must have remained doubtful.

When a portion of the mucous membrane of a true digestive stomach is examined, stretched upon a plane surface under water, we observe it to exhibit a multitude of small cells more or less circular in form. These cells are present over the whole surface, where a thick epithelium visible to the naked eye does not exist, and their presence may be considered to be characteristic of the true digestive surface, as contrasted with that of a simple macerating cavity. When the mucus has been well cleared away, we can see to the floor of each cell, which exhibits from three to five perforations, often rendered distinct by being filled with the white mucons secretion (fig. 1.) The cells are separated from

FIG. 1.

*This figure (from Bischoff) represents the cells seen on the surface of the stomach, with their floors perforated by the orifices of the tubes.*

each other by partition-like elevations of the membrane, which vary in depth, and sometimes even form pointed processes, mistaken by some anatomists for villi, which they really do resemble when examined on an oblique section. The diameter of the cells is about 1-180th inch to 1-250th inch: it varies, however, in the different regions, and is always largest near the pylorus. Such is the general description of the mucous surface of the stomach of all animals in which I have examined it—in man, the dog, cat, lion, the fourth stomach of ruminants, in the pig, rabbit, horse, and ass; in the simple stomachs of the frog and waternewt, in the stomach of the turtle, and in those of the skate and cod, in the former of which each cell measured 1-360th of an inch.

When the vessels of the stomach have been minutely injected with the size injection coloured red, nothing can be more beautiful than the vascular net-work which is then seen on the surface of the mucous membrane. The margin of each cell is surrounded by a vasenlar circle, which is joined at various points of its circumference by minute vessels emerging from the substance of the membrane, (fig. 3), and all the circles anastomose with each other. I know nothing which more forcibly exhibits the intricacy of the capillary vessels themselves than this vascular net-work on the surface of the gastric mucous membrane.

Although the appearance which I have described is rendered visible by a lens of very low magnifying power, so low as three or four diameters, no trace of it can be seen by the naked eye. The orifices of the so-called gastric glands, which Sir Everard Home states may be seen at the pyloric and cardiac portions of the mucous membrane of the stomach of man and other animals, can correspond to nothing but the cells which I have described; yet it is difficult to imagine, if he really did see these cells at the cardia, how he could have avoided seeing them, similar in arrangement although different in size, all over the mucons surface. Not unfrequently a remarkable series of smaller

wrinkles is seen on the pyloric and cardiac portions of the membrane. Three slight and very short fissures radiate from a central depression, and these occur in so great numbers, and at such regular distances from each other, that they are not unlikely to be mistaken for a peculiar structure, nor to be set down as glands, by those who are zealously in search of a distinct series of such organs in connection with the stomach. I have seen this appearance many times on the human stomach, and always in that of the pig; and I am disposed to think that it is produced by the contraction of the muscular coat, although I am unable to explain exactly the manner in which it is effected.

When thin sections of the mucous membrane, cut vertically to the surface, are placed under the microscope, they are seen to be composed of a number of tubuli closely applied to each other side by side, their blind extremities being in contact with the submucous tissue, and their free extremities opening into the bottom of the cells. In some situations these tubuli are straight and short; in other parts they are longer, and at their blind extremities present an appearance which might arise either from a slight convolution of the tube, or from some irregular dilatations of it in that situation (fig. 2). It very commonly

FIG. 2.

*Tubes from the pyloric portion of the stomach, as seen by a vertical section.*

happens that two tubuli coalesce or anastomose at their free extremities, and they will consequently open upon the floor of a cell by a common orifice; and hence it is that a greater number of tubules actually pour their contents into a cell, than would be indicated by the number of openings which pierce its floor. The diameter of the tubuli varies from 1-360th to 1-540th of an inch.

The tubuli are straiter and shorter at the cardiac portion of the stomach, longer and more convoluted, or irregular, at their blind ends, at the pyloric portions. In a

vertical section of an injected specimen, we see the vessels coming up from the submucous tissue, and passing between the tubuli, as in the annexed figure (fig. 3), to terminate in the vascular net-work on the surface.

FIG. 3.

*Vertical section of the mucous membrane, shewing the vessels passing to the superficial network (from Bischoff.)*

From the examination of thin horizontal sections at various depths of the membrane, I have ascertained that the tubuli are arranged in bundles or groups, surrounded and bound together by a fine cellular membrane, the bundles varying in size, and in the number of tubules contained in them, as shewn in fig. 4, which represents such a section of the dog's stomach, magnified about 100 diameters.

FIG. 4.

*Transverse section of the tubuli in the dog.*

When a very thin horizontal section taken from the free surface of the membrane is placed under the microscope, the free surface being upwards, and covered with talc or thin glass, a very beautiful view of the mouths of the cells, and the arrangement of the membrane around and

between them, is obtained. When viewed with an object-glass of a quarter of an inch focus, the membrane surrounding each cell appears raised, so as to form around each cell a prominent circle, from which the membrane inclines downwards into the cell; and if the section have gone below the level of the floors, we can see that the membrane is continued to the perforated floor of each cell.

From similar sections we are enabled to see very clearly the arrangement of the epithelium on the surface. I have already stated that the absence of a thick epithelium, visible to the naked eye, is characteristic of the true digestive stomach. An epithelium, however, nevertheless exists, of a very definite arrangement, which is distinctly brought into view by the use of high powers, of a quarter and eighth of an inch focus, and we are indebted to Henle for the first complete demonstration of the existence of an epithelium upon the whole mucous tract, from the mouth to the anus. My observation, however, does not confirm the statements of this anatomist with respect to the gastric mucous membrane: I have never seen the cylindrical form of epithelium in any part of the stomach. The whole surface of the membrane, on the contrary, appears to be as it were covered with a pavement of fine polygonal epithelium scales, which under the highest power present an appearance very similar to that of shagreen. The scales not only occupy the space between the cells, but pass over their margins, and are continued down to their floors. The diameter of the scales, in the dog, in the cardiac portion of the stomach, was from  $1/3100$ th to  $1/2325$ th of an inch. These scales resemble very much those of the deep layer of oesophageal epithelium, both in form and dimensions.

The matter contained in the tubuli appears to be of a very different nature from the scales of the epithelium: it is a soft, whitish substance, composed of minute granules, which exhibit no trace of structure even under the highest powers. This matter may be readily obtained by pressure from the tubes, in which it always exists in considerable quantity: it is in every respect the same as the layer of mucus which covers the membrane of the recent stomach.

In my examination of the stomach of the porpoise I observed that the mucous membrane of the second and third cavities was destitute of cells; it nevertheless is composed of vertical tubes similar to those found in the digestive stomach of other animals; a structure first noticed by Cuvier, and subsequently described by Sir David Brewster. These tubes, then, instead of opening into the bottoms of

cells, open at once upon the surface. Their mean diameter is  $1/360$ th of an inch: they are long in proportion to their diameter, and straight, not exhibiting the convoluted or irregular appearance at their blind extremities, which we have noticed in the carnivorous stomach. On an injected portion of the membrane the vascular circles were seen of a similar nature to those before described. The mucous membrane of the fourth stomach exhibited cells of an oval form,  $1/1538$ th of an inch wide, and  $1/1025$ th of an inch long. The cells were shallow, and the tubes short and indistinct, excepting at the termination of the membrane where it passes into that of the fifth cavity: here the tubes were distinct and long, and in the fifth stomach they acquire the same characters which they possess in the second and third.

The structure of the mucous membrane of the proventriculus or true digestive stomach of birds demands a separate description. Here it will be recollected the membrane presents a multitude of large follicles, which open into the cavity of the proventriculus. Each follicle may be considered as a little stomach in itself: when a simple follicle is laid open in its long diameter we observe a number of minute orifices on its internal surface, which are those of a series of tubuli arranged side by side, and vertically to its wall. The annexed figure (fig. 5) is a diagram repre-

FIG. 5.

*Vertical section of a simple follicle of the proventriculus in the pigeon.*

senting a vertical section of one of these follicles in the pigeon: the tubes in this bird are all short and straight, and measure

in diameter from 1-540th to 1-720th of an inch. The free surface of the membrane lining the cavity of the proventriculus is covered by a delicate epithelium; the scales of a less distinct character than usual, polygonal, but with one or two of the angles rounded off.

The follicles of the proventriculus of the ostrich are of the most complex kind: into each follicle a series of smaller and simple follicles pour their secretions, so that one of these compound follicles may be said to represent on a small scale the proventriculus of the pigeon. Each of the smaller follicles has exactly the structure of the simple follicle of the pigeon. The compound follicle, then, consists of an aggregate of simple follicles placed side by side, and vertically to the walls of the large ones, whilst each simple follicle consists of an aggregate of tubuli as before described. The epithelium is very distinct on the surface of the proventriculus, on which also there are numerous triangular processes not unlike villi.

From the preceding description of the structure of the mucous membrane of the digesting stomach in the vertebrata, we may not improperly designate this membrane as a gland; its constituent tubes being arranged perpendicularly to an extended surface, and pouring their secretions into a number of cells; not, as in other glands, into one or more canals or duets.

The change which the food undergoes in the stomach has long been known under the name of *chymification*; it consists in a total breaking down of the substance of the alimentary materials, into a soft semi-fluid mass, in which the natural texture and chemical composition of those substances are altogether changed. Albumen, for example, when introduced in a fluid state into the stomach, is first solidified, and then brought back again to the fluid state, from which it is not capable of being again solidified, or at least as completely as before. And starch, which has been thus acted upon in the stomach, is, according to Tiedemann and Gmelin, converted into gum of starch and sugar. Gelatine, moreover, loses, after digestion in the stomach, its property of gelatinising spontaneously; the various forms of animal and vegetable food become so broken down and dissolved as to be no longer recognizable; moreover, when substances are of such a nature as to resist the influence of the powers of the stomach, whatever they may be, they generally pass through the intestinal canal comparatively unaltered, inasmuch as there is no part of that canal in which they meet with the same solvent or reducing principles as are found in the stomach.

It is well known that the chymifying powers of the stomach have been from an early period ascribed to the influence of a special secretion, from the walls of the organ; an hypothesis first advanced and in a great measure proved by Reaumur, whose observations were published in the year 1752, in the memoirs of the Académie des Sciences; Reaumur's views were shortly afterwards confirmed by Spallanzani and Stevens, and subsequently by John Hunter; and within the present century have received the most ample confirmation from a great number of sources, of which I may mention Tiedemann and Gmelin in Germany, Dr. Prout in this country, and Dr. Beaumont in America. This fluid, the *gastric juice* of authors, is always acid, and when removed from the body and placed at a temperature of 100°, exerts a similar power over the alimentary substances submitted to it as in the stomach. It became important, therefore, in order to determine to what the solvent powers of this secretion were due, to ascertain its chemical constitution; and although the present imperfect state of organic chemistry scarcely enables us to determine, with perfect certainty, the true constituents of this fluid, it may be stated as the most probable result of the various analyses to which it has been subjected, that the gastric fluid contains water, with various neutral salts, free muriatic and probably also acetic acids.

Various experiments were instituted with a view to ascertain how far fluids, formed artificially in imitation of the gastric juice, would produce similar effects on the different kinds of food, which accordingly were subjected to the action of various chemical mixtures, containing acetic and muriatic acids alone or together, more or less diluted; and the negative result at least was obtained, namely, that no artificially formed fluid appeared to act upon the alimentary substances submitted to them, at all in the same way that the gastric fluid does. Whilst experimentalists succeeded perfectly in producing artificial digestion, by the aid of the gastric fluid taken from the stomach, they entirely failed when they had recourse to artificial fluids, made in imitation of the natural secretion.

To a German physiologist, Eberle, author of an interesting work on digestion\*, we owe the discovery of the cause of the failure in these experiments, and I cannot but regard his discovery as one of the most important of modern times. Having fail-

\* Physiologie der Verdauung nach Versuchen auf natürlichem und künstlichem Wege. Wurz- burg, 1834.

ed in a great variety of experiments on artificial digestion, with a view to ascertain the cause of failure he applied himself to investigate the condition of the stomach during the chymifying process. He was struck with the large quantity of mucus which is always poured out upon its surface as well as upon that of the food, during that process. In the latter situation Eberle had observed the mucus adhering to the surface of the mass of food, in the form of an expansion so like the membrane of the stomach that he at first supposed it to be that membrane removed with the food; he found that this mucus existed in greatest abundance at the earlier periods of stomach digestion, and that in the later periods it became subdivided, and portions of it were mixed with the food. When the alimentary matters are chiefly of a fluid nature, this mucus was not so readily detected, from its being diluted and mixed to a greater extent with the contents of the stomach. The mucus deposited during digestion is of a greater consistence than that which ordinarily lubricates the gastric surface; it is invariably acid, and these characters are found in the true digesting stomach, whether in the simple carnivorous form, or in the fourth stomach of the ruminant, or the proventriculus of birds.

This mucus diffuses readily in water, forming a thin acid fluid, by the action of which Eberle had the satisfaction of finding that fibrin, coagulated albumen, casein, &c. were in a short time completely chymified; substances which he had hitherto failed in affecting by any of the artificial mixtures containing the acids of the stomach. In fine, this mucus is the substance which we have already described as being poured out by the vertical tubes of which the mucous membrane consists, and it is to the organic principle which it contains that the acid secretion owes its solvent powers. The failure in former experiments was due to the non-existence in the artificially formed fluids of the organic principle derived from this mucus. Schwann, who has performed a very complete series of experiments on artificial digestion, gives to this principle the name of *Pepsin*.

A fluid possessing similar powers to that just described may be easily made by infusing in distilled water a portion of rennet, (fourth stomach of the calf) previously well washed, and adding some muriatic acid. I find that the following proportions answer extremely well; six grains of rennet carefully washed till all acid reaction has ceased, two drams of distilled water, and six drops of muriatic acid. The following experiment, which I have several times repeated and shown, will

serve as an illustration of the powers of this liquid. Two drachms of the fluid, prepared according to the formula above given, were put into a test tube, and small pieces of raw beef and mutton, together with a portion of boiled white of egg, cut in a cubic form, were immersed in it. Into a second test tube two drams of distilled water, three drops of muriatic and three drops of acetic acid, and pieces of the same alimentary substances, were put; and in a third tube the pieces of meat and albumen were immersed in two drams of distilled water, to which were added six drops of muriatic acid. The three tubes were kept for twelve hours at a temperature of 100° Fahr., and at the end of that time the following were the changes noticed in the albumen and meat. In the first test tube the albumen was reduced to a complete pulp; the meat was similarly softened, so that all appearance of its proper texture had completely vanished, and it broke down under the slightest pressure. The rennet also was completely disintegrated. In the second tube the cube of albumen had acquired at the edges a beautiful transparency, and here it had become almost of a fluid consistency: it was also very much softened in the centre. The meat was greatly softened, as in the first tube, gelatinized on its surface, and the rennet was reduced to a pulp. In the third tube no change had taken place beyond that which was evidently the result of the imbibition of fluid by the portions of meat and albumen.

The digestive fluid may be prepared by infusing the rennet in distilled water and muriatic acid, in the proportions already stated, at a temperature of 100°, for twelve hours: it must then be strained, and set aside for use. A clear straw-coloured fluid is thus obtained, exhibiting a decided acid reaction, with an agreeable smell, and not unpleasant flavour. This fluid will keep for a considerable period. I have some now by me which has kept unchanged for twelve months, and which shows no disposition to change. The digestive power of this liquid is destroyed if it be subjected to boiling, and likewise if it be neutralized by the addition of alkali, but it recovers its power again if the acid be restored. I am not without hope that it may be found useful as a therapeutic agent, in assisting the chymifying powers of the stomach, but my experience of its effects has been too limited to enable me to speak with confidence on this point.

Time warns me that I must content myself with this brief allusion to the observations of modern physiologists, which, as it appears to me, lead to the conclusion that the great agent of stomach-digestion

is the secretion which, under the influence of appropriate stimuli, is poured out from every point of the mucous membrane of the physiological stomach.

### ON SYPHILIS.

By HERBERT MAYO, F.R.S.

Senior Surgeon to Middlesex Hospital.

[Continued from page 385.]

[For the London Medical Gazette.]

*Progress and treatment of the ulcerative form of secondary syphilis — Cases exemplifying ulcerative psoriasis, lepra, tubercle, ecthyma, rupia.*

ULCERATIVE cutaneous disease constitutes the most formidable, but happily the least frequent, variety of secondary syphilis.

The complaint usually declares itself in a few weeks after the appearance of the primary sore. It is sometimes ushered in by pains in the back, and shoulders, and limbs; but the eruption with which it commences is partial, and seems insignificant; often amounting to no more than an incrustated patch upon the head, or a few leprous spots, or one or two patches of rupia on the shoulders, or three or four phlyzacious pustules on the legs. The throat is liable to be simultaneously attacked, when ulceration either of the tonsils or pharynx manifests itself, which for a time appears the more serious affection. It rarely, indeed, happens that the two progress with equal virulence. The latter, as will subsequently be considered, is liable to remain the principal malady. But if, in the other case, the skin disease advances, the ulceration of the throat is found to give way to the remedies employed, and commonly does not reappear, the subsequent attacks of sore throat throughout the malady being limited to excoriation.

The present form of constitutional syphilis differs from the scaly and the lichenous, especially in this, that after the first outbreak has taken place, instead of being mitigated, it is for a period either steadily progressive or after each remission it returns with increased virulence. Yet there are not wanting cases that display a comparatively mild character throughout; in

which, for instance, no symptoms may be present beyond partial ulceration of the eyelids, or in which two or three ulcers on the body and limbs alone occur, leaving the patient after the lapse of a few months or a year, not worse in constitution and not disfigured. With these milder forms, however, there are liable to be combined iritis, and nodes upon the bones, which in the worst cases seldom supervene.

But in the most cases, if exempt from these, the remaining features are tremendous. The head covered with painful encrusted ulcers; the eyebrows ulcerated, and partially or wholly destroyed; the soft parts of the nose eaten away, or falling in from ulceration of the cartilaginous septum; the spongy bones necrosed; the palate carious; the tonsils and tongue swollen and excoeriated; the gums spongy and sore; ptyalism present, with horrible fetor of the breath; the ears tumefied and raw; phagedænic ulcers on the body and limbs, with sympathetic contraction of the joints. Such ravages are liable to take place in the natural course of the disease; but their heightened and most frightful character is only seen when the effects of mercury, in aggravating every symptom, and inducing general caries of the bones, are superadded.

As the habitudes of the disease are changed in this variety, so should be the principles of treatment. No good is here to be obtained by giving way to the disease; its manifestations, on the contrary, should be from the first repressed by every available means.

The remedy principally to be relied on is the iodide of potassium, which commonly requires to be administered in doses of a scruple three times a day; but it is proper to begin with smaller doses, giving at first five or seven grains only, and gradually increasing the quantity, which may thus be raised to half a drachm, with half a grain to a grain and a half of iodine in combination. I have not had occasion to go beyond this dose, and have in most cases found all the good to be obtained from the remedy obtainable by less. Sometimes it will appear prudent to continue the use of the iodide in scruple doses three times a day for two or three months at a time; when it happens that, although fresh ulcers are continually breaking out, while the first are

healing, yet on the whole the patient's strength and general condition are progressively improving under the treatment. In other cases the influence of the iodide is temporary only, and to re-acquire efficiency it must be disused for a fortnight or longer, and this frequently. Change of air is often highly beneficial in ulcerative syphilis; but least so at its most virulent period. It tells most when the complaint is on the turn, or when it exists in a less aggravated form. Opium is beneficial, first by calming pain, and giving sleep; secondly, by preventing the iodide of potassium from disordering the system. Stimulants, as it will be supposed, are often necessary; wine or brandy, with the most nutritious food the stomach will bear. Mercury in general does so much harm in ulcerative syphilis that one is unwilling to admit it in the list of remedies. Nevertheless, when the health is unbroken, and mercury is new to the constitution, either at the beginning or in the progress of the disease a brief course of mercury is occasionally serviceable; sometimes it may be advantageously combined with the exhibition of the iodide. In mild cases, as in syphilitic ulceration of the eyelids alone, mercury is found to be as efficient as the iodide; but it only removes the symptoms, and the iodide will do the same equally quickly, and with more safety to the patient's constitution. The local treatment of ulceration of the throat will be adverted to afterwards, but something has here to be said of the local management of the cutaneous sores.

The two best applications are the unguentum plumbi cum cretâ, and strong aqueous solutions of opium. Mercurial applications commonly cause pain, but occasionally lime-water and calomel, lime-water and corrosive sublimate, the white precipitate ointment, and even mercurial fumigation, prove beneficial. Washing the sores with a solution of nitrate of silver always does temporary good, but the practice is objectionable on account of the pain it gives.

I have now to illustrate the features and treatment of ulcerative lues by the detail of cases; and I shall first take occasion to advert to those instances in which the forms of the disease already treated of approach the present.

It has been observed that lepra is transitional between the scaly and the

ulcerative varieties of secondary syphilis; that scattered spots of psoriasis will occasionally lead to superficial ulcers; and that clustered psoriasis will sometimes originate spreading ulceration. Among the out-patients of the Middlesex Hospital is one of the name of John Robinson, who presents the most aggravated instance of clustered psoriasis that I have witnessed. He has been under my care four years, with this history:—He assures me that, to his knowledge, he has had no disease of the genital organs for the last ten years; that then he had an ulcer, and went through a course of mercury; that he continued in perfect health for from four to five years, when he was attacked with pains, and an eruption on the skin, and sore throat, for which he underwent treatment. When he came under my care, four years ago, he had clustered psoriasis on the forehead, head, back, and loins, with considerable ulceration upon the back. He took the iodide of potassium for a long time, and recovered; he has had repeated relapses since, but the eruption has not since gone to the extent of ulcerating. When the disease returns, which it commonly does within a month after its remission, he recommences the iodide, and gets well again; he is now just emerging from an attack. I have tried mercury in this case, both alone and in conjunction with the iodide, but it does not disperse the eruption more quickly, and it weakens him. He is otherwise in perfect health and strength. In time it is evident that, with the assistance of the iodide, he will wear out the disease, and retain an unbroken constitution, which, if mercurial treatment had been pursued, would long ago have sunk under it. The next case in inveteracy that I remember, of clustered psoriasis going on to ulceration, took place in a remarkably athletic middle-aged man, and followed indurated chancre, which healed under not less than a two months' course of mercury. The psoriasis appeared before the mercurial course had terminated. The course, however, was begun late; the sore had existed from a fortnight to three weeks when the patient came under my care.

Of lepra, it has been mentioned that the greater number of cases may be prevented passing into ulceration; and in the passages extracted from Willan

and Carmichael, mercury was the remedy spoken of as capable and necessary to arrest its progress. The latter observation does not accord with my own experience; in siphilitic lepra I have found the iodide of potassium much more efficacious than mercury, and have seen the ulcerative form assumed by the complaint during the use of mercury, after which its progress has been stopped by the iodide. However, there are natural differences in the tendencies of siphilitic lepra that deserve attention. Certain cases are more disposed to go into ulceration than others. When the blotch enlarges quickly, leaving the centre where it began pale and without scales, and the spreading edge is not much elevated or thickened, there is less likelihood of virulent ulceration; and the ulceration, if it occur, will probably be superficial only, like that of psoriasis. It is when the skin is thickened and tuberculous, and the patch enlarges slowly, and is covered with some thickness of cuticular scale, that ulceration is most threatened, and that mercury should be abstained from, and the iodide given in its stead.

The following case exemplifies the most virulent lepra:—

John O'Shaughnessy, in the autumn of 1828, had a primary ulcer and bubo, for which he took mercury. Before long leprous eruption and ulceration of the throat followed. He was admitted into Middlesex Hospital, in January 1830, with several large leprous spots on his limbs and body; a large ulcer on the instep, another on the shoulder. He took liq. potassie, with sarsaparilla, and the ulcer on the instep healed. But lepra broke out universally. The patches became covered with a great thickness of papery scales, the skin beneath which felt thickened: the scales became a crust, and falling off disclosed an ulcer. There were many of these ulcers on the limbs and body; the forehead and face were covered with them. The lips, the alae of the nose, the eyebrows, were equally involved in ulcerated blotches. The patient suffered from burning heat of the body and face, and the ulceration of the lips produced pytalism. The bones were not affected, but there was pain on moving the joints of the legs, and a small depôt of serous matter formed in the right calf. Every remedy was now tried in succession, and all did

temporary but very transient good, except nitric acid with bark, and mercury: these medicines made him worse. Having had him under my care a year, and the disease being unsubdued, I then ordered (Dec. 1830) at M. Magendie's suggestion, who happened to see the patient, a sixth of a grain of iodine, with ten grains of the iodide of potassium, three times a day. The good effects of the remedy were apparent after a few days: the skin became less red and heated, several of the crusts separated, and the ulcers put on a healthy appearance. In a month the patient had made a great amendment. But now the amendment ceased. The iodide was therefore discontinued; upon which the patient became worse. After a fortnight he resumed the medicine, with the same advantage as on first taking it. In a month the disease became again stationary. He then discontinued the iodide, to resume its use in a fortnight. By these means in five months he recovered his strength and health; but a few blotches would occasionally appear, upon which he again had recourse to the iodide. Afterwards a very severe relapse took place, of which he was cured in the Lock by the same medicines. When I last saw him he had been quite well for some years.

Ulcerative tubercle, again, exhibits very different degrees of virulence. In one case under my care, occurring in a man sixty years of age, in which the disease followed primary phagadenic ulcer, and was attended with iritis, the ulcers that formed in the tubercles were shallow, and soon healed. In another case, which occurred in a gentleman towards fifty, whose constitution had been tried in India, the primary sore for which I attended him being phagadenic, a few cutaneous tubercles formed, which became shallow indolent ulcers, and were subordinate to painful glandular swellings, which slowly arose in the neck and in the groin: each of these in succession came forward and opened, and for several months continued a deep foul indolent ulcer. They all, however, gradually dried up under the interrupted use of the iodide of potassium.

The following cases exemplify some more common varieties of tubercular ulceration:—

Henry Morrison, aged 39, subject to gleet for several years, in December, 1838, contracted a sore on the corona

glandis, for which he took three or four pills every day for two months. The mouth was only affected during the last week of the mercurial course; but he had numbness first of one finger, then of a second, and of the right side of the under-lip, following acute pain in it, and in the head. The two former after a while disappeared; the last symptom still remains. The ulcer healed in five weeks from the commencement of the mercurial course, but about the same time incrustated sores formed on the back of the head and sides of the face, and on the shoulders, and the throat became sore. He took sarsaparilla and other medicines, and became better, but relapsed, and finally, in June, came under my care as an out patient of Middlesex Hospital, with a large and painful ulcer on the calf of the right leg. He was ordered fifteen grains of the iodide of potassium three times a day, in decoction of sarsaparilla, and the dose on those days was increased to twenty-four grains. But it produced no salutary effect; the sore was as painful as before, and the integument of the nose became red, threw off thin scales, and threatened to ulcerate. He then took a twelfth of a grain of corrosive sublimate three times a day with temporary advantage; but becoming worse he was admitted into the hospital in July. The iodide was then resumed in the dose of four grains twice a day, increased after a week to eight, and the ulcer was dressed with Peruvian balsam ointment. It gradually healed, but his face became heated, the integuments of the nose red and cracked, and a disposition to ulcerate manifested itself on the chin. Corrosive sublimate was now very reasonably prescribed (not indeed by myself), and afterwards blue pill; but the disease was on the advance, and the patient thought it made worse by these remedies. He then tried decoction of sarsaparilla with liquor potassæ, then decoction of bark with nitric acid, then quinine with dilute sulphuric acid, with no advantage. The iodide was tried in small doses; but now, in the smallest, it produced the severest headache, and he became weaker, the nose having ulcerated, and incrustated spots forming on the cheek and lower part of the face; so all medicine was discontinued but occasional purgatives, and I allowed him full diet and porter. He became

stronger, but the ulceration continued virulent, and extended itself. Then I tried the iodide again, with seven drops of laudanum to each dose, and giving at the same time active aperient medicine almost every night. Under this plan the patient improved considerably; the crust separated from the nose, the ulcer upon which is healthy, and healing rapidly; but some heat and crusted spots remained on the sore part of the face. Then the face became more heated again; the iodide has therefore been temporarily relinquished; the purgative is taken every night, and his face appears cooler and better.

John Saxon, aged 31, was admitted into the Middlesex Hospital in 1830, with secondary symptoms, which followed a venereal sore and a course of mercury. More than a year before, the integuments of the forehead became at two points puffy and tender, but not discoloured: these spots soon became red, and broke, and then for many months the face was disfigured in the following manner:—There were oblong narrow ulcers of an irregular outline on the forehead, eyebrows, and bridge of the nose; the skin around each was red and swollen, but soft; these ulcers spread, healing at one extremity, and extending at the opposite: in this way both his eyebrows were destroyed. Every remedy had been tried, and each for a few days with transient benefit. I then prescribed iodine and the iodide of potassium: amendment followed, which was rapid and uninterrupted, and the patient became perfectly well. He afterwards had a slight relapse, which was cured by the same means. I have seen him within the present year, and he has since been in perfect health.

W. Donovan, aged 38, admitted into the Middlesex Hospital October 11, 1836, eight weeks ago observed an ulcer upon the glans, for which he took seven pills, one each night; his gums became tender, and the ulcer healed. But he experienced general indisposition, and had pain in the back. Twelve days ago either a tubercle or pustule formed on the lower eyelid, giving rise to an ulcer, which has spread. He took one pill again at night for a week, beginning October 3: this brought back the tenderness of the gums, which, however, had remained spongy and tumefied. During that week his throat be-

came sore, and an ulcer formed at the orifice of the penis. At his admission the whole of the cutaneous aspect of the lower eyelid was occupied by a foul sloughy ulcer. There was a yellow excavated ulcer of the right tonsil, which was red and swollen: at the orifice of the penis there was a similar ulcer. The compound decoction of sarsaparilla with carbonate of soda was ordered, and Peruvian balsam applied to the eyelid. On the 15th, some amendment; seven grains of the iodide of potassium, in decoction of sarsaparilla, now prescribed three times a day: in two days more a considerable improvement had taken place. On the 21st, the ulcer of the eyelid was healing at the lower margin; the ulcer of the throat was well, and the ulcer of the urethra healing. On the 26th, the iodide, which had produced headache and gastric irritation, was discontinued. The patient left the hospital a fortnight afterwards, well; but the same form of disease afterwards returned: the patient was not then under my care.

Hannah Gregory, aged 42, towards Christmas 1837 contracted a venereal discharge, which lasted three months. Before it was well several spots appeared on her chest and neck, which she describes as having been red and elevated; their surface became crusted over, and they ulcerated; and the throat became sore, and new spots, similar to the first, appeared on the body and thighs, and on the forehead and face, which likewise crusted and ulcerated. She took pills and sarsaparilla, and in the course of two or three months all the sores, except some upon the face, had healed, when she was admitted into the hospital, and took sarsaparilla and mercurial pills for a month. She was something better, but erysipelas of the head and face supervened, which reduced her extremely, and she remained some time in the hospital for the recovery of her strength. On leaving it she went into the country for two months, and returned to London quite well, and continued so about three months. Soft tubercles leading to incrustated ulcers then reappeared, and after some months she became my patient, being readmitted in July 1839, with ulcers of the face, a large ulcer on the right thigh, and two upon the left. These ulcers were extremely painful,

pricking, shooting, burning. She was ordered a scruple of the iodide of potassium three times a day, in decoction of sarsaparilla; this, subsequently increased by the addition of half a grain of iodine to each dose, she has taken till the present time, with the exception of a fortnight in October. During this period her health and general appearance have improved, and all the sores, including several upon the face, body, arms, and legs, which have broken out while she has been in the hospital, have healed but one. The sores which have latterly broken out have begun by tubercular thickening and encrusting of some part of the edge of an old cicatrix.

W. Woodgate, aged 22, admitted into Middlesex Hospital Feb. 12, 1837. The preceding October an ulcer had formed at the side of the frænum, which was destroyed by it. The surgeon who attended him endeavoured for two months to heal the sore without mercury. Then the ulcer spreading, five-and-twenty grains of blue pill were given daily for three weeks, which produced salivation, and the ulcer healed. A fortnight, however, had barely elapsed before he observed a hardness about the spongy body, an inch from the orifice of the penis, and in a short time ulceration took place at the junction of the inner prepuce with the body of the penis, and matter was discharged from a cavity between the thickened integument and the spongy body. At his admission the gums were sore from the remaining effect of the former mercurial course, and a few pills he had taken the preceding week. One tonsil was superficially ulcerated, and on the top of his head was a crust of the size of a sixpence, covering an ulcer. The penis was extremely painful. A probe introduced between the thickened integument and spongy body passed into an ulcerated canal three inches in depth; this was laid open, and a large extent of sloughy surface exposed. A carrot poultice was ordered, with opium at night. Under this treatment the surface became clean, and granulated for the most part healthily. But after a few days at two parts the surface put on the phagedænic character; it was yellow, with red points shewing through it, and soft; the adjoining integument thickened, red, and angry. Feb. 28th, the phagedæa spreading, and having eaten a con-

siderable hole into the urethra, nitric acid was applied to the whole ulcerated surface; and the decoction of bark, with dilute nitric acid, ordered. The ulcer had a much healthier appearance on the superficial slough separating: Peruvian balsam was ordered to be applied to it, and on March 4th a scruple of the iodide of potassium, with a grain of iodine, to be taken daily in place of the bark. The ulcer now contracted rapidly, when, about the end of March, the medicine having been discontinued, the ulcer began at one part to put on anew the phagedænic character, and at the same time the ulcer of the throat, which had never quite healed, became more sore, and the ulcer of the scalp began to discharge and spread; and seven or eight soft tubercles formed on the thighs and legs, which ran into ulcers. April 8th, these symptoms increasing, the iodide was resumed with daily improvement; the ulcer on the penis became perfectly healthy; those on the legs were covered with pale granulations. April 22d, the ulcers on the leg and head again spread. The largest on the leg was of a pale grey, with maroon coloured spots shewing through it; the margin inclined to yellow, with a dusky red border of skin. I then determined to try mercury again, which, administered in the form of blue pill, and the ointment, produced considerable swelling of the mouth, with pyalism. The action was kept up for three weeks, and the medicine then discontinued, leaving, however, for three weeks more, some impression on the mouth. In a few days from commencing the mercurial course great amendment took place, and he completely recovered.

The following case exemplifies ecchyma:—

Thomas Edwards, aged 17, admitted July 10th, 1827. He had had gonorrhœa six weeks, and a foul flat sore on the foreskin three weeks: on the legs there were a few large pustules. He was put upon mercury; other pustules appeared, but few in number, on his body and arms, and one on his forehead. The primary sore healed, but the pustules became painful ulcers, which, however, after a time began to granulate healthily, and healed. Mercury was then discontinued, after a course of two months' duration. Three weeks after discontinuing mercury the cicatrices

began to burn at night; and two, one on the right instep, the other on the left ham, ulcerated anew. The ulcers were extremely painful; but he had rather gained flesh, and had no night sweats. Oct. 25th, ten grains of blue pill to be taken every night. 29th, the ulcers more painful; his joints stiff; a drachm of strong mercurial ointment every night; the pills omitted. Nov. 16th, he has grown fatter; the mercury has just begun to affect the gums, which remained slightly touched till Dec. 26th, when the mercury was discontinued. Before this several other cicatrices had ulcerated. The ulcer on the ham had elongated itself, and the middle part had healed; each end had a yellow phagedænic edge, against a raised border of angry integument. The ulcers are rather better after the application of nitrate of silver in substance, or solution, or of the yellow wash. Fumigation, the black wash, the Peruvian balsam, have done rather harm than good. Decoction of sarsaparilla, with the extract, ordered. Jan. 10th, ulcers still spreading. The forehead tender, and swollen at one part; painful node upon the tibia. Decoction of bark, with fifteen drops of muriatic acid, three times a day, ordered. 20th, great improvement; the ulcers have healed, the white precipitate ointment having been the local application. Feb. 18th, the nodes on the forehead and tibia are less, and without pain. There is an ulcer at the back of the pharynx; ordered to be touched with the linimentum æuginis. He soon after this went out nearly well.

The two following cases exemplify siphilitic rupia:—

Sarah Holloway, aged 24, in April 1837 had an ulcer of the labium, with discharge. She took two pills night and morning for a fortnight, and the gums were affected. The sore healed in three weeks from its first appearance. A fortnight afterwards she came to London, when her throat became sore, and continued so for six weeks, during part of which time she took medicine, and her mouth was again slightly affected. Three weeks after her recovery the sore throat returned, and continued several weeks. It was healed by being touched with lunar caustic. In August 1837 a crusted sore formed at the back of the head, and afterwards a

second; afterwards a sore formed upon the shoulder, and her throat became again ulcerated. She was admitted into the Middlesex Hospital in April, and remained four months. She had crusted ulcer on the hand at her admission, excavated ulcer of the tonsils, and a sore upon the shoulder. She at first took sarsaparilla with the iodide of potassium, became better, and then ceased to improve, when the oxy muriate of mercury was substituted for the iodide, but with no advantage: the former ulcers became more angry; rupia appeared in several patches in succession upon the arms and legs. Ultimately the iodide of potassium was resumed, and she became well. In January 1839 she was readmitted for five weeks with similar symptoms, from which she emerged on taking the iodide. In July she returned, and staid in again two months: at the commencement of this period corrosive sublimate was again tried, when she became worse; but on resuming the iodide, which she took in the dose of a scruple three times a day, she became well. She returned a few weeks ago with crusted ulcer of the head, and a node on the tibia; for this the iodide was again ordered, and when I last saw her she was improving.

Elizabeth Chilcott, aged 42, became an out-patient of the Middlesex Hospital during the winter before last; she had patches of rupia upon the shoulders and limbs, the greater part of her face was tuberculous and ulcerated, the ears were swollen and excoriated, and she was profusely salivated. Some months before she had had discharge and sores, and swelling in the groin, for which she had taken mercury. While her mouth was sore secondary symptoms had appeared; she had sore places on the head, and her throat was ulcerated she says. However, she became better. After an interval the symptoms, for which she again took mercury, became aggravated till they reached their present state. I ordered the iodide of potassium in decoction of sarsaparilla, which produced immediate improvement; and in from four to five months, during which the disease was occasionally stationary, or progressive even, for a few days at a time, she had recovered. All this time she took the iodide, which was increased to half-drachm doses three times a day, and latterly,

for a short period, combined with an eighth of a grain of corrosive sublimate twice a day. She remained well for about four months. In the autumn her former symptoms reappeared. Mercury was again administered, and she fell into a state of disease more aggravated than before. She then reapplied to me, and was admitted into the hospital at Christmas 1838, with tuberculous ulcers of the face, and encrusted and open ulcers on her back and limbs, and the right turbinated bone necrosed. I drew away the dead portion of bone, and prescribed again for her the iodide of potassium. She improved, but temporarily only; and although the medicine was continued, the disease extended its ravages: her head and face were covered with encrusted ulcers; her back and abdomen, and her limbs, were covered with the same, or with open ulcers, and several fresh eruptions of rupia appeared every few days. Among the flat vesicles which became encrusted, full round bladders would form and break, and the surface appear excoriated, and then either go on to ulcerate, or scab and heal. Then other remedies were tried, bark with nitric acid, and the other antisiphilitic medicines, without effect. At night she took opium. The use of the iodide was then resumed, and steadily persevered in, the dose being continually increased. From May 18th to June 19th she took three times a day half a drachm of the iodide, with first a grain, then a grain and a half, of iodine. At this time she experienced pain in the head, and extreme giddiness; but she had become materially better, most of the ulcers had healed, few new vesicles now appeared, and she suffered considerably less pain. The iodide was now discontinued against her wish. She remained for a time nearly stationary, then fell back again. Corrosive sublimate in small doses having been given, she became worse. Then, in the latter end of August, I prescribed the iodide anew, in scruple doses; it had great efficacy, having been disused so long. She improved rapidly, and in October left the hospital nearly well. A month ago she returned with two or three small ulcers on the thigh and leg, that were angry and painful; but she resumed the iodide, and appears to be now all but well.

[To be continued.]

## SMALL-POX AND VACCINATION.

*To the Editor of the Medical Gazette.*

SIR,
